Veterinary Pharmacology and Therapeutics

EDITED BY **H. RICHARD ADAMS**

Blackwell
Publishing

H. RICHARD ADAMS has specialized in veterinary pharmacology and pathophysiology, with emphasis in cardiovascular and autonomic drugs and research in circulatory shock. He has taught pharmacology to veterinary medical students and medical students for 30 years. He was on the faculty in the Department of Pharmacology at the University of Pittsburgh and in the Department of Pharmacology of Southwestern Medical School at the University of Texas Health Science Center at Dallas. He served as Professor in the Department of Pharmacology in the School of Medicine, Professor and Chairman of the Department of Veterinary Biomedical Sciences, and Dean of the College of Veterinary Medicine at the University of Missouri, Columbia. He holds Professor Emeritus and Dean Emeritus titles from the University of Missouri and is an Honorary Diplomate of the American College of Veterinary Emergency and Critical Care. Dr. Adams currently is Dean of the College of Veterinary Medicine at Texas A&M University, College Station. He is a member of the American Academy of Veterinary Pharmacology and Therapeutics, the American Society of Pharmacology and Experimental Therapeutics, the American Physiological Society, and the Shock Society (serving as its 1994–1995 president). He received B.S. and D.V.M. degrees from Texas A&M University and a Ph.D. degree in pharmacology from the University of Pittsburgh.

Preface ix

Section 1. Principles of Pharmacology 3

1. Veterinary Pharmacology: An Introduction to the Discipline *Scott Anthony Brown and Lloyd E. Davis* 3
2. Pharmacodynamics: Mechanisms of Drug Action *Mark J. Novotny* 9
3. Pharmacokinetics: Disposition and Fate of Drugs in the Body *Scott Anthony Brown* 15
4. Clinical Pharmacology: Principles of Therapeutics *Mark J. Novotny* 57

Section 2. Drugs Acting on the Autonomic and Somatic Nervous Systems 69

5. Introduction to Neurohumoral Transmission and the Autonomic Nervous System *H. Richard Adams* 69
6. Adrenergic Agonists and Antagonists *H. Richard Adams* 91
7. Cholinergic Pharmacology: Autonomic Drugs *H. Richard Adams* 117
8. Neuromuscular Blocking Agents *H. Richard Adams* 137

Section 3. Drugs Acting on the Central Nervous System 153

9. Introduction to Drugs Acting on the Central Nervous System and Principles of Anesthesiology *Eugene P. Steffey* 153
10. Therapeutic Gases: Oxygen, Carbon Dioxide, Water Vapor, and Nitric Oxide *Eugene P. Steffey* 172
11. Inhalation Anesthetics *Eugene P. Steffey* 184
12. Injectable Anesthetics *Keith R. Branson* 213
13. Opioid Agonists and Antagonists *Keith R. Branson and Marjorie E. Gross* 268
14. Tranquilizers, α_2-Adrenergic Agonists, and Related Agents *Marjorie E. Gross* 299
15. Local Anesthetics *Khursheed R. Mama and Eugene P. Steffey* 343
16. Anticonvulsant Drugs and Analeptic Agents *Dawn M. Boothe* 360
17. Drugs Affecting Animal Behavior *Dawn M. Boothe* 383
18. Euthanizing Agents *Eugene P. Steffey* . . . 397

Section 4. Autacoids and Anti-inflammatory Drugs 403

19. Histamine, Serotonin, and Their Antagonists *H. Richard Adams* 403
20. Peptides: Angiotensin and Kinins *H. Richard Adams* 413
21. Prostaglandins, Related Factors, and Cytokines *H. Richard Adams* 420
22. The Analgesic, Antipyretic, Anti-inflammatory Drugs *Dawn M. Boothe* 433

Section 5. Drugs Acting on the Cardiovascular System 453

23. Digitalis and Vasodilator Drugs *H. Richard Adams* 453
24. Antiarrhythmic Agents *H. Richard Adams* 482

Section 6. Drugs Affecting Renal Function and Fluid-Electrolyte Balance . . 501

25. Principles of Acid-Base Balance: Fluid and Electrolyte Therapy *Deborah T. Kochevar* 501
26. Diuretics *Deborah T. Kochevar* 534

Section 7. Drugs Acting on Blood and Blood Elements **553**

27. Antianemic Agents *Martin J. Fettman and H. Richard Adams* 553

28. Hemostatic and Anticoagulant Drugs *H. Richard Adams* 571

29. Blood and Blood Components *Dawn M. Boothe* 586

Section 8. Endocrine Pharmacology **593**

30. Hypothalamic and Pituitary Hormones *Duncan C. Ferguson and Margarethe Hoenig* 593

31. Hormones Affecting Reproduction *Frederick N. Thompson* 612

32. Thyroid Hormones and Antithyroid Drugs *Duncan C. Ferguson* 626

33. Glucocorticoids, Mineralocorticoids, and Steroid Synthesis Inhibitors *Duncan C. Ferguson and Margarethe Hoenig* 649

34. Drugs Influencing Glucose Metabolism *Margarethe Hoenig* 672

Section 9. Nutritional Pharmacology **683**

35. Fat-Soluble Vitamins *Martin J. Fettman* 683

36. Water-Soluble Vitamins *Martin J. Fettman* 702

37. Calcium, Phosphorus, and Other Macroelements *Martin J. Fettman* 722

38. Trace Elements and Miscellaneous Nutrients *Martin J. Fettman* 744

Section 10. Chemotherapy of Microbial Diseases **783**

39. Antiseptics and Disinfectants *Mark C. Heit and Jim E. Riviere* 783

40. Sulfonamides *Jerry W. Spoo and Jim E. Riviere* 796

41. Penicillins and Related β-Lactam Antibiotics *Shelly L. Vaden and Jim E. Riviere* 818

42. Tetracycline Antibiotics *Jim E. Riviere and Jerry W. Spoo* 828

43. Aminoglycoside Antibiotics *Jim E. Riviere and Jerry W. Spoo* 841

44. Chloramphenicol and Derivatives, Macrolides, Lincosamides, and Miscellaneous Antimicrobials *Mark G. Papich and Jim E. Riviere* 868

45. Fluoroquinolone Antimicrobial Drugs *Mark G. Papich and Jim E. Riviere* 898

46. Antifungal and Antiviral Drugs *Mark G. Papich, Mark C. Heit, and Jim E. Riviere* 918

Section 11. Chemotherapy of Parasitic Diseases **947**

47. Antinematodal Drugs *Craig R. Reinemeyer and Charles H. Courtney* 947

48. Anticestodal and Antitrematodal Drugs *Craig R. Reinemeyer and Charles H. Courtney* 980

49. Antiprotozoan Drugs *David S. Lindsay and Byron L. Blagburn* 992

50. Ectoparasiticides *Byron L. Blagburn and David S. Lindsay* 1017

Section 12. Specialty Areas of Pharmacology **1041**

51. Drugs Affecting Gastrointestinal Function *Dawn M. Boothe* 1041

52. Chemotherapy of Neoplastic Diseases *Kenita S. Rogers and Gordon L. Coppoc* 1064

53. Dermatopharmacology: Drugs Acting Locally on the Skin *Jim E. Riviere and Jerry W. Spoo* 1084

54. Drugs Affecting the Respiratory System *Dawn M. Boothe* 1105

55. Ophthalmic Pharmacology *Cecil P. Moore* 1120

Section 13. Regulatory Considerations **1149**

56. Legal Control of Veterinary Drugs *Stephen F. Sundlof* 1149

57. Dosage Forms, Drug Prescription Orders, and Veterinary Feed Directives *Scott Anthony Brown* 1157

58. Chemical Residues in Tissues of Food Animals *Jim E. Riviere and Stephen F. Sundlof* 1166

PREFACE

Welcome to the 21st century and the eighth edition of *Veterinary Pharmacology and Therapeutics*. The first edition of this textbook was authored almost 50 years ago by a pioneer in veterinary pharmacology, Dr. L. Meyer Jones. He dedicated the first edition primarily to professional students learning pharmacology as part of their quest to become doctors of veterinary medicine. Now, almost one-half century and seven revisions later, the eighth edition of *Veterinary Pharmacology and Therapeutics* is likewise dedicated to veterinary medical students enrolled in professional colleges and schools of veterinary medicine.

The authors and editor of this text have compiled in one book a comprehensive resource for students to learn basic and applied principles of veterinary pharmacology and therapeutics. Although this textbook is directed to the professional veterinary student, expanded coverage of pharmacology has broadened its audience to also include graduate students in the biomedical sciences, residents and interns in medicine and surgery, laboratory animal specialists, and research investigators who utilize animals, to name just a few. Furthermore, because practicing veterinarians who already have earned their DVM or VMD are lifetime students of veterinary medicine, this text is also intended as a desktop reference for veterinary practitioners to review details about drugs, drug mechanisms, and their clinical applications. The authors and editor sincerely seek critical feedback from students, practitioners, academic colleagues, and others as to whether the book is meeting its goals and how future editions can be improved.

Veterinary pharmacology has changed dramatically in many complex ways since the first edition of this textbook was published. This evolving complexity is reflected in the changing faces of the different editions of this book. A single veterinary pharmacologist, Dr. Jones, was able to author the entire textbook in excellent fashion by himself in 1954. By the third edition in 1965, several more contributors had joined Dr. Jones, and by the seventh edition in 1995, more than two dozen authors were necessary to adequately cover the breadth of veterinary pharmacology necessary for the "fountainhead" textbook in this field. Pharmacology and its sister disciplines, veterinary pharmacology and veterinary clinical pharmacology, have simply become too complex to be adequately covered by only a few authors. We are fortunate that the eighth edition includes chapters authored by 27 contemporary pharmacologists, each one a recognized and well-published expert in some aspect of veterinary pharmacology and veterinary clinical pharmacology.

The 1990s witnessed an explosion of new drugs and increased understanding of the cellular and molecular mechanisms responsible for the pharmacodynamic actions of both new and older pharmacologic agents. However, the full clinical relevance of such exciting discoveries is adequately understood only in a few cases. This textbook focuses on those aspects of pharmacology that have clinical applications in veterinary medicine and surgery. Attempts were not made to address every available drug or to continue to discuss older drugs that are infrequently used. Rather, the authors focused on basic mechanisms of representative drugs from the most important classes of therapeutic agents. An understanding of basic drug mechanisms and their pharmacotherapeutic applications in the presence of disease provides the basis for problem solving in clinical medicine. We believe this approach provides the most effective way to learn pharmacology and therapeutics, rather than rote memorization of pyramiding facts.

This edition includes considerable revision of existing materials, again reflecting the changing contents of veterinary pharmacology. A new chapter, "Drugs Affecting Animal Behavior," was added to reflect the expanding importance of animal behavior and its therapeutic modulation. Continuing its success from the seventh edition, a section on specialty areas of pharmacology was included to cover those important aspects of pharmacology that overlap multiple facets of pharmacotherapeutics which do not readily fit into single traditional drug groups.

As the editor of this textbook, I have the pleasure of expressing appreciation to the many people who made the eighth edition of *Veterinary Pharmacology and Therapeutics* a reality. Sherry Adams provided special contributions as my staff assistant, and Dr. Gheorghe Constantinescu of the University of Missouri College of Veterinary Medicine provided several original illustrations. We are all indebted to Dr. L. Meyer Jones for his pioneering contributions as a veterinary pharmacologist and educator and for establishing this textbook. Special acknowledgment also goes to former editors Dr. Nicholas H. Booth and Dr. Leslie E. McDonald for leading this textbook through earlier revisions necessary for its transition into the modern era of veterinary pharmacology. Special recognition and appreciation also are extended to Dr. Lloyd Davis, a retired former author and major contributor to veterinary pharmacology for many decades. Dr. Davis helped secure disciplinary stature for veterinary pharmacology and was central to formation of the American Academy of Veterinary Pharmacology and Therapeutics and the American College of Clinical Veterinary Pharmacology.

It is especially important to acknowledge and thank all the authors: the authors of previous editions, who composed the foundation upon which we now stand, and the new authors for assuming the responsibility to prepare new chapters and to update previous ones. Our common goal is to help carry forth the tradition of excellence set by previous editions of *Veterinary Pharmacology and Therapeutics* and to provide the seminal resource for veterinary pharmacology and therapeutics that will help the veterinary profession successfully enter the 21st century.

H. Richard Adams

Veterinary Pharmacology and Therapeutics

8th
Edition

SECTION 1

Principles of Pharmacology

1

VETERINARY PHARMACOLOGY: AN INTRODUCTION TO THE DISCIPLINE

SCOTT ANTHONY BROWN AND LLOYD E. DAVIS

Scope of Pharmacology
Role of Pharmacology in the Veterinary Medical Curriculum

Throughout recorded history, humans have employed drugs for treating disease as well as for social and religious purposes. Sir William Osler (1849–1919), a prominent medical educator of the latter 19th century, stated, "A desire to take medicine is, perhaps, the great feature which distinguishes people from other animals."

The discovery of drugs was undoubtedly through the process of trial and error as people tried various plant, animal, and mineral substances in their environment as potential sources of food. Through such activity it soon became apparent that ingestion of certain plants would produce diarrhea or vomiting and that chewing the bark of trees would cause constipation. It was then probably recognized that if one were suffering from diarrhea, ingestion of tannins in bark would relieve symptoms. Such accumulated knowledge gave rise to oral traditions within tribes, and a folklore on drugs developed.

Primitive tribal folklore evolved into attempts to organize knowledge of drug substances. The earliest written compilation of drugs is the Chinese herbal formulary *Pen Tsao,* which is attributed to Emperor Shen Nung, who lived in about 2700 BC. Veterinary and human medicine were well developed in Asia Minor during antiquity. Ancient Hindu records mention eating chaulmoogra fruit to treat leprosy. The Code of Hammurabi (about 2200 BC) described penalties for malpractice by practitioners. The oldest record of Egyptian drug codification is the Kahun papyrus, which was written about 2000 BC. It deals with veterinary medicine and uterine disease of women and contains a number of prescriptions. The Ebers papyrus (1550 BC) is a compilation of a number of disease conditions and 829 prescriptions for medicaments employed in Egyptian medicine. Medicine also was highly developed in Sumeria during the millennium preceding the Christian era. Evidence for this is provided by a library of clay tablets assembled by Ashurbanipal (626–568 BC) and discovered at Nineveh during the 19th century.

The codified drug lore of Egypt was transmitted to Greek civilization. Foremost among early Greek physicians was Hippocrates (460–375 BC), a great teacher of medicine. There formed about him a group of physicians known as the Hippocratic school. They were astute diagnosticians and brilliant surgeons who maintained high ethical standards. They had little use for drugs, as they recognized that sick people usually tended to get well regardless of treatment. This concept of the healing power of nature became known as the *Vis medicatrix naturae*. A precept from the Hippocratic school, which still provides an ethical basis for the practice of therapeutics, is "Above all, do no harm." Both these concepts had to be relearned again and again throughout subsequent history. Hippocratic physicians adapted the notion of a humoral basis for disease from philosophers in Asia Minor. The four elements of natural philosophy were water, fire, air, and earth. Combinations of these elements gave rise to four humors of the body related to a scale of life from most alive to death. They were blood (sanguine temperament), phlegm (phlegmatic), yellow bile or urine (bilious), and black bile (melancholic). Treatment consisted of attempting to balance these humors by replenishment of deficiencies or removing excesses. Thus arose the practices of bleeding, purging (including vomiting), and sweating that continued well into the 19th century. Hippocrates also promoted the use of inorganic salts as medicine.

Works of Galen (131–201) dealing with physiology and materia medica became authoritative and were used widely for the next 1400 years. Galenic medicine consists of preparations of plants by soaking (infusion) or boiling (decoction). Galenic medicine has rebounded today as more people embrace herbal remedies. A scientific basis for medicine was begun by Aristotle (384–322 BC), who made and recorded numerous observations on animals. His pupil Theophrastus (380–287 BC) systematically classified medicinal plants on the basis of their individual characteristics rather than their recommended use in treatment. This work was improved upon by Dioscorides, a surgeon with the armies of Nero, who compiled the first *Materia Medica*. This treatise consisted of six volumes describing about 600 plants. Drugs were discussed from the standpoint of name, source, identification, tests for adulteration, preparation of the dosage form, what it would do, and for what conditions it would be used. This contribution was important because it established the framework for later pharmacopeias (officially recognized books of drug preparations). With the decline of the Roman Empire, scholarship transferred to Byzantium, where during the 5th century Publius Vegetius compiled a veterinary treatise that included prescriptions for farm animals.

Following the fall of Rome, Europe entered the Dark Ages, during which time there was little advancement in intellectual development. Custodians of knowledge and developers of medical thought during this period were found in Muslim culture. They developed the practice of pharmacy to a high level and were the first to distill wines and beers to obtain ethanol for preparing tinctures. Also they were the first to regulate the practice of pharmacy to standardize the preparation of prescriptions. An influential Persian writer during this period was Geber Ibn Hajar (702–765). He classified drugs and poisons of his time and recognized that the difference between a drug and a poison was a matter of dosage. Any drug can be toxic if given in large enough amounts.

The spirit of inquiry was reestablished in Europe during the Renaissance and was given impetus by the development of printing. The first pharmacopeia was compiled by the German Valerius Cordus (1514–1544). He carefully described techniques to be employed in preparation of drugs, in marked contrast to the secrecy prevailing prior to his time. The most influential person during this period was the Swiss physician Theophrastus Bombastus von Hohenheim (1493–1541), who called himself Philippus Aureolus Paracelsus. He introduced the clinical use of laudanum (opium) and a number of tinctures of various plants, the active principles of which are used to this day. He advocated using drugs in a directed or rational manner as opposed to the following of recipes.

The 17th and 18th centuries were an era of nationalism and flowering of individual genius. Drug trade flourished and medical experimentation began. Drugs such as cinchona (quinine), coffee, tea, and cocoa (methylxanthines), curare, digitalis, and a variety of alkaloids were discovered. The energetic and brilliant English physician John Hunter (1728–1793) influenced a group of physicians to conduct controlled clinical experimentation. The most notable contribution to therapy was William Withering's (1741–1799) *An Account of the Foxglove and Some of Its Medical Uses*, published in 1785. His observations on the use of digitalis in the treatment of dropsy (ascites due to congestive heart failure) are still pertinent. Edward Jenner (1749–1823) discovered and established the principle of prophylactic immunization against smallpox and was the first to describe anaphylaxis. Thus he set the stage for later development of preventive medicine and immunologic therapy. William Harvey (1578–1657) discovered the circulation of blood and indicated that drugs were distributed to various parts of the body by this means. The great English architect Christopher Wren (1632–1723) made the first intravenous injection of drugs into a dog, but it was not until 1853 that the hypodermic needle and syringe were devised by Alexander Wood (1817–1884). This was to have a major influence on later pharmacologic experimentation. During this period scientific societies developed as scientific information was disseminated. Pharmacopeias were well developed at this time and were the principal sources of information concerning drugs. Prescriptions were carefully devised by the practitioner for treatment of the individual patient.

The 19th century marked the development of chemistry, which paved the way for detailed characterization and experimental study of active pharmacologic principles derived from natural sources. Friedrich Sertürner (1783–1841), a German pharmacist, isolated the specific narcotic substance from opium and named it morphine after Morpheus, the Roman god of sleep. There followed in rapid succession isolation of active alkaloids from a variety of medicinal plants through the work of Joseph Caventou (1795–1877), Pierre Pelletier (1788–1842), Philipp Geiger (1785–1836), Georg Merck (1825–1873), and Albert Neimann (1840–1921).

The association between Pelletier and François Magendie (1783–1855) led Magendie to develop organized experiments to elucidate physiologic processes and action of drugs in the body. Magendie and his illustrious pupils Claude Bernard (1813–1878) and James Blake (1814–1893) established the foundations for modern pharmacology and outlined its unique scientific problems: dose-response relationships, drug disposition in the body, mechanism of action of drugs, site of action of drugs, and structure-activity relationships. The first laboratory devoted exclusively to the study of pharmacology was established by Rudolph Buchheim (1820–1879) at the University of Dorpat in Estonia. Extensive research was performed there to elucidate actions of drugs within the body. This stimulated development of pharmacology as a distinct scientific discipline. One of Buchheim's students, Oswald Schmiedeberg (1838–1921), was an excellent teacher who attracted students from around the world to the pharmacology institute of the University of Strasbourg. He led in establishing pharmacology as an independent scientific discipline based upon experimental methodology. Many of his students became leaders in the development of pharmacology throughout the world. These included Hans Meyer (1853–1939) at Vienna and John J. Abel (1857–1938), who is regarded as the "father of pharmacology" in the USA. Abel established departments of pharmacology at the University of Michigan and later at Johns Hopkins University. He trained many young scientists who became prominent pharmacologists. He founded the *Journal of Biological Chemistry* and *Journal of Pharmacology and Experimental Therapeutics* and was instrumental in the formation of the American Society of Pharmacology and Experimental Therapeutics (Abel 1926).

During the 20th century the science of pharmacology flourished in the medical and pharmacy schools, and the focus of leadership shifted from Europe to the USA. This was due in part to the occurrence of two world wars and the emergence of the USA as an industrial power. The almost exponential growth of knowledge and development of new drugs during this century were the result of the development of organic chemistry and the existence of an abundance of well-trained scientific investigators. The ability of chemists in the pharmaceutical industry to synthesize new chemical substances removed our dependence on natural products as a source of drugs. All aspects of the science progressed rapidly during this century, with appreciable gains in effective treatment and control of diseases. Most notable has been development of drugs effective in the treatment of infectious diseases. For a more detailed and scholarly review of the historical development of pharmacology, the reader is referred to Leake 1975 and Burger 1986.

The development of veterinary pharmacology is the same as that for humans. Throughout much of medical history little distinction was made between human and animal medicine, and both professions share common roots. Early European schools of veterinary medicine were established in conjunction with schools of human medicine. Near the beginning of the 20th century the two professions and their schools separated and developed more or less independently. Since that time a cultural lag has existed between human and veterinary medicine due to differences in size and economic factors. The teaching of materia medica as a didactic course persisted in veterinary schools until the early 1950s. Little was known or taught about pharmacology of drugs in domesticated animals.

L. Meyer Jones was instrumental in shifting emphasis in the veterinary curriculum from materia medica to the science of veterinary pharmacology. The decisive event in this transition was publication of the first edition of this textbook by Jones in 1954. As with most aspects of veterinary medicine, veterinary pharmacology has lagged behind its human counterpart by several years. Today, however, veterinary pharmacology is a vital part of veterinary medical education and research. Several professional organizations are dedicated to the furtherance of veterinary pharmacology as a research and clinical discipline, including the American Academy of Veterinary Pharmacology and Therapeutics, the European Association of Veterinary Pharmacology and Toxicology, the European College of Veterinary Pharmacology and Toxicology, and the American College of Veterinary Clinical Pharmacology.

SCOPE OF PHARMACOLOGY. *Pharmacology* is an experimental science dealing with the properties of drugs and their effects on living systems. It has included study of sources of drugs (pharmacognosy), action and fate of drugs in the body (pharmacodynamics), use of drugs in the treatment of disease (therapeutics), and poisonous effects of drugs or xenobiotics (toxicology). The word *drug* is derived from the Old French *drogue*, which meant herb. Drugs have been defined officially by the US Food, Drug, and Cosmetic Act to include all articles recognized in the *United States Pharmacopeia* (USP) and the *National Formulary* (NF); articles intended to be used in the diagnosis, mitigation, treatment, or prevention of disease in humans or other animals; and articles other than food intended to affect the structure or function of the body.*Pharmacodynamics* refers to study of the response of an organism to the action of drugs in the absence of disease. *Pharmacotherapy* refers to the use of drugs in the treatment of disease, whereas *therapeutics* is a term describing treatment of disease in general and includes use of drugs, surgery, radiation, behavioral modification, and other modalities. *Pharmacokinetics* is defined as the mathematical description of temporal changes in concentration of drugs and/or their metabolites within the body (Baggot 1977). Such studies provide the experimental basis for drug dosage regimens in various animal species.

Clinical pharmacology is considered in human medicine to be synonymous with human pharmacology (Smith 1978). In its broader sense, *clinical* means "pertaining to or founded on actual observation and treatment of patients, as distinguished from theoretical or basic sciences" (Anderson 1994). The discipline forms a foundation for the application of pharmacologic principles in the development of drug therapy for animal patients (Brumbaugh and Davis 1987). Controlled evaluation of the efficacy and safety of drug therapy in animal patients is a major concern of veterinary clinical pharmacology.

Chemotherapy is a branch of pharmacology dealing with drugs that selectively inhibit or destroy specific agents of disease such as bacteria, viruses, fungi, and other parasites. Use of this term has been extended to the use of drugs in treatment of neoplastic diseases. The notion of selective toxicity is central to chemotherapy. Drugs that are useful as chemotherapeutic agents affect the pathogen or abnormal cell more adversely than normal cells of the host.

Toxicology classically has been defined as the study of poisons. The subject is concerned with the adverse effects of xenobiotics. Its scope classically includes not only drugs used in therapy but also the many other chemicals that may be responsible for household, environmental, or industrial intoxication through food additives, industrial wastes, radioactive substances, pesticides, and ingestion of natural substances (Benet 1996). Others have defined toxicology as the science that defines the limits of safety of chemical agents for human and animal populations (Casarett 1996).

Posology is the study of medicine dosage, which varies with the species of animal, the intended effect of the drug, and individual tolerance or susceptibility. In general, the effective dose of a drug is that amount necessary to elicit the desired therapeutic response in the patient. The student should differentiate between the terms *dose* and *dosage*. A dose is the quantity of medication to be administered at one time, whereas dosage refers to determination and regulation of doses.

Metrology is the study of weights and measures as applied to preparation and administration of drugs. The reader is referred to Chapter 57 for a more complete discussion.

Pharmacy is a separate and complementary health care profession concerned with collection, preparation, standardization, and dispensing of drugs. By training, the pharmacist is well-equipped to advise the veterinarian on matters relevant to dosage forms, incompatibilities, drug interactions, and medicinal chemistry as well as to fulfill the traditional role of compounding and dispensing appropriate dosage forms of drugs.

Materia medica is an obsolete didactic subject that was concerned with pharmacy, posology, pharmacognosy, and indications for therapeutic use of drugs. This subject was purely descriptive in nature and has been replaced in the modern veterinary medical curriculum by the science of comparative pharmacology.

Nutraceuticals are nutritional products which allegedly have some therapeutic value in addition to their scientifically recognized nutritional content. These are not regulated as drugs by the US Food and Drug Administration and as such do not have the supporting data regarding their safety or efficacy for the alleged (or implied) claim.

ROLE OF PHARMACOLOGY IN THE VETERINARY MEDICAL CURRICULUM. The purpose of an education is to assist the individual in becoming an independent person who can think. Veterinary medical curricula are designed to facilitate the acquisition of factual material, skills, and an understanding of concepts to enable the student to practice the profession of veterinary medicine. Practice is the application of knowledge, skills, and thought for purposes of maintaining the health of animals, relieving suffering, and serving the best interests of the clients. Thus the student must endeavor to understand the concepts and facts of the veterinary medical sciences to be able to make decisions regarding diagnosis, treatment, and management of animal patients.

Pharmacology, like pathology, is a bridging medical science in that its study is dependent on an understanding of anatomy, physiology, microbiology, biologic and organic chemistry, and mathematics. Conversely, thorough understanding of pharmacology, toxicology, and pathology is requisite to studies of internal medicine, surgery, and other clinical subjects.

The number of products—from approved drug products to nutraceuticals and homeopathic remedies—that can be acquired worldwide and used legally by the practicing veterinarian is staggering. Literally hundreds of new products become available every year, although only a very few are new compounds, and even fewer are approved new animal drugs. While this growth in available therapeutic products has provided an unprecedented armamentarium of potent pharmacotherapeutic agents, it has also greatly increased the incidence of therapy-related disorders (iatrogenic diseases). No one can have an intimate knowledge of all drugs available, and even if it were possible, it would be unnecessary to the optimal medical care of animal patients. Efforts are being made by educators in veterinary pharmacology to define the 50–100 drugs essential to the practice of veterinary medicine for detailed discussion in veterinary pharmacology courses and emphasis in clinics. Monographs describing several of these veterinary drugs appear in the *United States Pharmacopeia Dispensing Information.*

The veterinarian must keep in mind that there is no completely "safe" drug unless the compound is pharmacologically inert. Thus the art of rational therapeutics requires consideration of potential risks as well as possible benefits of drugs to the patient's well-being

(Nierenberg and Melmon 1992) and consideration of the public health implications of such intervention. Considerable risk might be tolerated in treatment of a life-threatening disease, whereas even a small risk might be unacceptable in management of a self-limiting disease. The veterinarian must, therefore, understand the actions of the drug on the body, how it is absorbed and eliminated, its toxic effects, its clinical indications and contraindications, and its dosage in the species of animal to be treated. The student should attempt to incorporate this specific information into an intellectual framework of pharmacologic principles. Subsequent chapters of this book will develop the ideas underlying veterinary pharmacology and provide specific information concerning a number of drugs.

A convenient guide for the student to organize a course of study has been developed (Coppoc and Stuckey 1977). The purpose of the Minimal Essential Drug Information Checklist (MEDIC) is to encourage a problem-solving approach to learning pharmacology, i.e., to ensure that the student possesses an adequate knowledge base to make rational decisions regarding use of a particular drug in a given patient. This checklist is given below with permission from the authors and publisher (Coppoc and Stuckey 1977):

DRUG

1. What is your therapeutic goal? What specific pathologic process do you wish to alter by using a drug from this class and this drug in particular? Is it absolutely necessary that you use this or any drug?

2. By what routes can the drug be given for the indication in question and which are you going to use? On what basis did you make this decision? What are, e.g., the relative advantages or disadvantages of intravenous vs. oral administration in this case?

3. What dosage form are you going to use?

4. What dose in units/kg or mg/kg is generally recommended and how much are you using in this particular animal? How did you arrive at this dose? Are there items considered under "precautions" that should modify the dose in this animal?

5. What is the dosage interval? Is this going to be frequent enough to prevent the drug from dropping below effective concentrations? Will it be too frequent and precipitate cumulation and toxicity?

6. What is the probable duration of therapy?

7. For food animals? Is the drug approved for use in this food-producing species? What is the withdrawal time?

8. How much does the drug cost per treatment and per expected duration of therapy? (This should include administration expenses such as syringes, technician time, and special dispensers as in a water supply.) Does the cost of treatment exceed the value of the animal or the desire of the owner to pay? Is the cost appropriate to the seriousness of the disease?

9. What special precautions must be observed to enhance its effectiveness or safety? Examples: What if the drug is eliminated by the kidney and renal function is compromised? Will the drug interact with other drugs in the regimen?

10. What are contraindications to the use of this drug; i.e., under what conditions should it not be used?

11. What adverse reactions might one reasonably expect to see? How would you monitor the animal to detect potentially serious reactions before they are permanent or endanger the animal's life?

12. What course of action will you take if you elicit one of the drug reactions outlined above? Do you have the requisite drugs and/or equipment on hand?

13. What plans do you have for evaluating the results of your therapy? By what parameter(s) will you judge whether the animal is responding to treatment? When can you reasonably expect to see the first response? How will you judge whether you have cured the animal? What follow-up procedures should be instituted?

Veterinary pharmacology is not an easy subject to master because of the multiplicity of species concerned and plethora of available drugs that can be legally obtained. The veterinarian is asked to care for the health of the entire animal kingdom with the exception of humans. In studying this text, the student should constantly be alert to the fact that various species of animals may respond differently to certain drugs. These species differences, and the fact that many of the animals we treat enter the human food supply, distinguish veterinary pharmacology from medical pharmacology.

Diligent study of comparative pharmacology is an essential part of becoming an effective veterinarian who is capable of applying or prescribing rational drug therapy without harming the patient. This has been a central problem of medicine since antiquity and continues to the present time.

As Aristotle (384–322 BC) said in *Nichomachean Ethics*, book 9, "Even in medicine, though it is easy to know what honey, wine and hellebore, cautery and surgery are, to know how and to whom and when to apply them so as to effect a cure is no less an undertaking than to be a physician [veterinarian]."

PHARMACODYNAMICS: MECHANISMS OF DRUG ACTION

MARK J. NOVOTNY

Pharmacodynamic Terms
  Receptor
  Agonists, Affinity, Efficacy, and Potency
  Antagonism
  Selectivity and Specificity
Quantitative Responses in the Patient
Quantitative Aspects of Drug-Receptor Interaction
Dose Titration Studies

Pharmacodynamics is the study of physiologic and biochemical effects of drugs and how these effects relate to a drug's mechanism of action. Pharmacodynamics focuses on the action and effects of drugs within the body. For example, a drug may interact with a receptor on the surface of a myocardial cell to initiate a series of reactions that cause the myocardial cell to contract more forcefully (a positive inotropic effect); the result is an increase in cardiac output and peripheral tissue perfusion, culminating in an increase in exercise tolerance of a patient with congestive heart failure. The study of the effects of a drug can span from basic biochemical and molecular mechanisms to cellular responses, to effects on organs or systems, to the whole animal, or even to populations of animals. Thus, pharmacodynamics is relevant to all aspects of pharmacology: from basic pharmacologic research in the laboratory to applied therapeutics in the clinical patient. In general, pharmacodynamics characterizes what a drug does to the patient. In contrast, the study of pharmacokinetics (Chapter 3) addresses what the patient's body does to a drug. The patient absorbs the drug into the systemic circulation, distributes the drug to tissues in the body, metabolizes the drug, and eliminates the drug from the body. Effective use of a drug requires knowledge of the drug's pharmacokinetic and pharmacodynamic properties.

PHARMACODYNAMIC TERMS. Important to the discussion of pharmacodynamics is an introduction to the terms used to define the pharmacodynamic properties of a drug.

Receptor. A *drug receptor* is the macromolecular component of body tissue with which a drug interacts to initiate its pharmacologic effects. Only the initial consequence of a drug-receptor interaction is correctly termed the "action" of the drug. The succeeding effects are more properly called drug "effects." Receptors can be proteins, enzymes, nucleic acids, or other cellular constituents. Protein receptors are often well characterized. Examples include the muscarinic receptors on cells of the heart, smooth muscle, or exocrine glands and nicotinic receptors on cells at neuromuscular junctions or preganglionic synapses. The endogenous neurotransmitter acetylcholine (ACh) activates both muscarinic and nicotinic receptors. The widely used drug atropine competes with ACh for muscarinic receptors as its mechanism of drug action.

Enzymes associated with key regulatory or metabolic processes are particularly useful receptors. As an example, the neurotransmitter ACh is metabolized by acetylcholine esterase (AChE), an endogenous enzyme that terminates the action of ACh. The drug pyridostigmine inhibits AChE, prolonging the action of endogenous ACh, and is therefore useful for treating myasthenia gravis, a disease characterized by a reduction in functional nicotinic receptors at neuromuscular junctions. In the presence of pyridostigmine, ACh is available longer to activate the remaining functional nicotinic receptors. As another example, the synergistic antimicrobial effect of the trimethoprim-sulfonamide combination results from actions on sequential steps in the enzymatic pathway by which microorganisms synthesize folic acid from precursor molecules.

Other cellular constituents can serve as receptors. Examples include nucleic acids, ion channels, and intracellular proteins such as tubulin, the respective sites of action of cancer chemotherapeutic agents, calcium channel blockers, and the antifungal agent griseofulvin. For certain drugs a therapeutic effect occurs in the absence of clearly defined, macromolecular tissue receptors. Examples include the osmotic diuretic mannitol (Chapter 26) and analogs of purine and pyrimidine bases (Chapter 52) that serve as suicide substrates for DNA or RNA synthesis.

Maximal tissue response to a drug may occur when only a fraction of the total number of receptors are occupied by the drug. This situation can come about, e.g., when a step subsequent to occupancy of the receptor by the drug is limiting the expression of the drug-receptor response. The term *spare receptor* applies to the situation when maximal response is elicited by occupancy of a fraction of the tissue receptors.

Agonists, Affinity, Efficacy, and Potency. An *agonist* is a drug that possesses affinity for a particular receptor and causes a change in the receptor that results in an observable effect. Agonists are further characterized as *full agonists,* producing a maximal response by occupying all or a fraction of receptors, or *partial agonists,* producing less than a maximal response even when the drug occupies all of the receptors. *Affinity* describes the tendency of a drug to combine with a particular kind of receptor, whereas *efficacy* or *intrinsic activity* of a drug refers to the maximal effect the drug can produce. A partial agonist has less intrinsic activity than a full agonist. *Potency* is a term that is frequently misunderstood when comparing two or more drugs that give rise to the same observable effect. Potency of a drug refers to the dose that must be administered to produce a particular effect of given intensity. Potency is influenced by the affinity of a drug for its receptor sites and by pharmacokinetic processes that determine drug concentration in the immediate vicinity of its site of action (biophase). Potency of a drug varies inversely with dose; the lower the dose required to produce a stated response, the more potent the drug. Potency is a relative, rather than an absolute, expression of drug activity. For potency determinations a standard must be defined, and potency comparisons are valid only for drugs that produce the stated response by the same mechanism of action. Potency of a drug is not necessarily correlated with its efficacy or safety, and the most potent drug within a series is not necessarily clinically superior. Low potency is a disadvantage only if the effective dose is so large that it is too costly to produce or too cumbersome to administer.

Antagonism. An *antagonist* is a drug that blocks the response produced by an agonist. Antagonists interact with the receptor or other component of the effector mechanism, but antagonists are devoid of intrinsic activity. Antagonists can be further characterized as *competitive antagonists* or *noncompetitive antagonists.* Competitive antagonism is completely reversible; an increase in the concentration of the agonist in the immediate vicinity of its site of action or biophase will overcome the effect of the antagonist. Although lacking intrinsic activity, the "efficacy" of an antagonist is measured in terms of reversing or blocking the effects of the receptor's agonist. Therapeutic agents acting by competitive antagonism include atropine (antimuscarinic agent), diphenhydramine (antihistamine or H_1-receptor blocker), propranolol (β-adrenergic blocking drug), and spironolactone (aldosterone antagonist).

A *noncompetitive antagonist* conceptually removes the receptor or response potential from the system. Addition of more agonist to the biophase of the inhibited receptor will not overcome the antagonism achieved by a noncompetitive antagonist. Thus the essential feature of noncompetitive antagonism is that the agonist has no influence upon the degree of antagonism or its reversibility. The maximal effect achievable by the agonist is reduced accordingly by a noncompetitive antagonist. Examples of noncompetitive antagonists include the α-adrenergic blocking drug phenoxybenzamine and the platelet-inhibiting action of aspirin. The thromboxane synthase enzyme of platelets is irreversibly inhibited by aspirin, a process that is reversed only by production of new platelets (Chapter 22).

Selectivity and Specificity. A drug is usually described by its most prominent effect or by the action thought to be the basis of that effect. However, rarely does a drug produce only a single effect; most drugs produce multiple effects. *Selectivity* of a drug depends on its capacity to preferentially produce a particular effect. The characteristic effect of the drug is produced at lower doses than those required to elicit other responses. For example, the sympathomimetic amine clenbuterol has a high degree of selectivity for β_2 receptors in airways and is useful in the treatment of respiratory disease in horses with bronchospasm. At high doses manifestation of activity on cardiac β_1 receptors may be apparent. A truly selective drug produces only a single effect. The anticoagulant heparin is an example of a drug that has selective action. For therapeutic applications, selectivity of a drug is one of its more important characteristics. The route of administration (e.g., topical administration) or the pattern of drug distribution to sites of action (e.g., restricted from the central nervous system) may confer selectivity of action on certain drugs that are ordinarily nonselective.

When all the effects produced by a drug are due to a single mechanism of action, the drug is said to be *specific.* A specific drug acts at only one type of receptor but may produce multiple pharmacologic effects because of location of receptors in various organs. Atropine is a specific drug in that its varied effects can be attributed to its antimuscarinic action. Effects of a nonspecific drug result from several mechanisms of action. The potential effects of phenothiazine tranquilizers (e.g., acepromazine) include sedation (increase the rate of dopamine turnover in the brain), an antiemetic action (depress activation of the chemoreceptor trigger zone), hypotension (α-adrenergic receptor blockade), an antispasmodic effect on the gastrointestinal smooth muscle (anticholinergic action), and hypothermia (interference with hypothalamic control of temperature regulation).

QUANTITATIVE RESPONSES IN THE PATIENT.

The purpose of administering a drug to an animal is to produce a particular response of desired intensity. This response will usually be produced by establishing and maintaining for a certain time an effective concentration of the drug in the immediate vicinity of its site of action. A fundamental principle of pharmacology is that the intensity of response elicited by a drug is a function of the dose administered. The response of a patient to different doses of a drug, or the dose-response relationship, conforms to the principles discussed below for drug-receptor interactions. The patient response can be represented graphically in at least two ways, as shown in Fig. 2.1. In Fig. 2.1A the relationship is depicted between the drug dose and the response. More commonly, the concentration of the drug is expressed on a logarithmic scale as shown in Fig. 2.1B. The slope of the log dose-response indicates the range of dosage over which the drug acts, from minimally detectable to maximally effective. The variability in the response can be related to physiologic, pathologic, or drug-induced variation in the patient or to variation in a population of patients. Thus, variability in effectiveness of a drug given to the same patient at different times or to different patients within the same species can be due to circadian changes, age, the state of the patient's health, genetic variation, or environmental effects, or it may be drug induced, as for instance by receptor down-regulation (see Chapter 4).

The relationship between dose and response may be interpreted in one of two ways: (1) as the dose of a drug is increased, the intensity of the response is increased (graded dose-response); or (2) as the dose is increased, the number or proportion of animals exhibiting a particular, stated response is greater (quantal dose-response). A graded dose-response relationship can be measured on a continuous scale, whereas a quantal response is an all-or-none response. Thus, for an individual patient, the dose-response may be graded or quantal depending on which criterion of response has been adopted. For example, if the response criterion for dogs with atrial fibrillation is reduction in the rate of contraction of the ventricles in response to increasing doses of the cardiac glycoside digoxin, then the ventricular rate can be measured on a continuous scale with an electrocardiograph. Therefore, the dose-response relationship is graded. However, if the response criterion is reduction of the ventricular rate to ≤140 beats per minute (bpm) for a population of dogs with atrial fibrillation, then the response of each dog to a given dose of digoxin will be all-or-none; the ventricular rate either did or did not decrease to ≤140 bpm for each animal. The more-sensitive dogs in the population may experience a decline in ventricular rate to ≤140 bpm at a relatively low dose of digoxin; more-resistant cases of atrial fibrillation will require higher doses. Thus, the effect of a drug and its variability can be monitored in a population, not necessarily by measuring the graded response in individuals in the population to a range of different doses, but by measuring the dose required to produce a measured effect among the individuals.

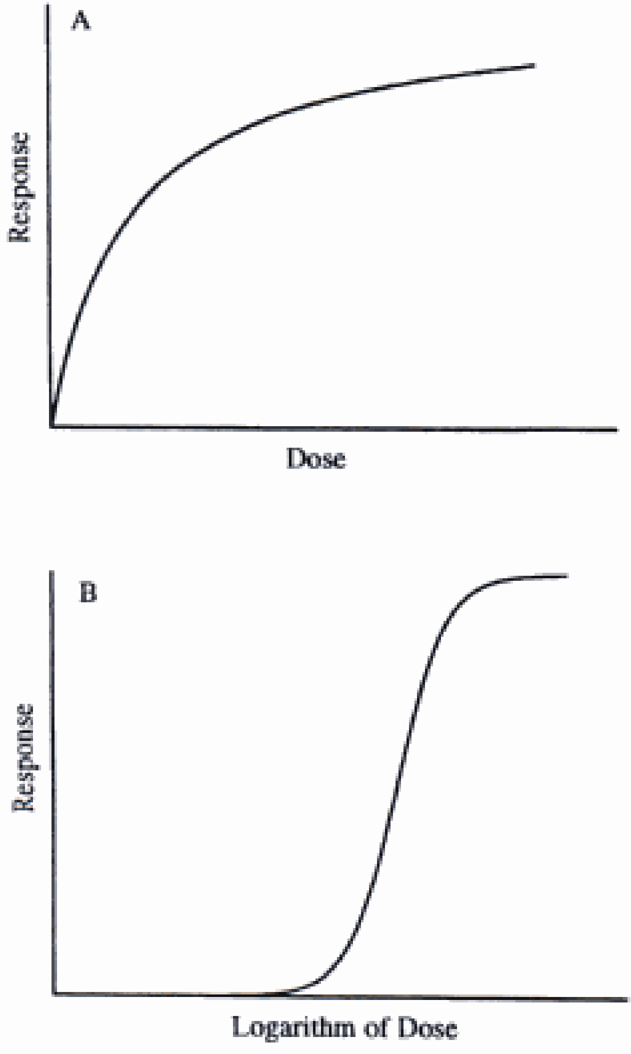

FIG. 2.1

In practice, an end point to a response or an effect is defined, and the dose of drug required to achieve that end point is determined in a group of individuals from the population. Fig. 2.2 shows the result of such a procedure. A frequency distribution curve is obtained with

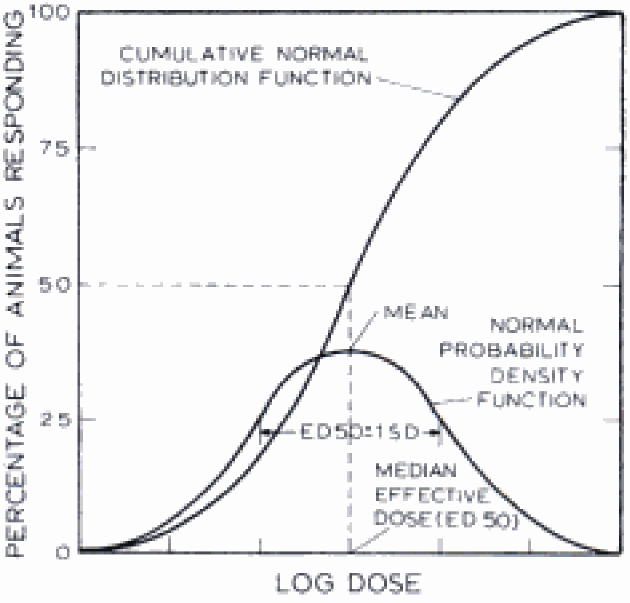

FIG. 2.2—Graphic presentation of the quantal dose-response relationship. Both normal and cumulative forms of the frequency distribution curve are shown.

the most-sensitive members of the population responding and reaching the end point at the lowest dose of the drug and with the most-resistant members of the population requiring the highest doses. As Fig. 2.2 illustrates, the sensitivity of a drug is distributed normally with respect to the logarithm of the dose. In this population, the dose required to produce the effect in 50% of the individuals is known as the *median effective dose* and is abbreviated ED_{50}. When the frequency distribution curve is plotted as a cumulative frequency distribution curve, the familiar logarithmic dose-response curve is obtained (Fig. 2.1B). This is the form of the curve commonly used for ease of understanding some of the principles of drug dosage.

At any given dose, the cumulative (quantal log dose-response) curve gives the percentage of animals responding to that dose and to all lower doses. Although both the graded and quantal dose-response curves are sigmoidal in shape, they represent different interpretations of the dose-response relationship. The graded curve relates the intensity of response to the size of dose (see below), whereas the quantal curve expresses individual variation in the dose needed to produce a specified (predetermined) response.

A useful measure of variability of the normal distribution curve is the standard deviation (SD). The area under the curve enclosed by 1 SD on either side of the median represents about 68% of the total area enclosed by the entire distribution curve (Fig. 2.2). That is, approximately two-thirds of the total number of animals tested would respond to a dose lying within 1 SD of the ED_{50}.

As noted previously, for the individual dose-response curve, the slope of the curve gives an indication of the range over which a drug elicits its effects. In a population, the slope is similarly important in indicating the range over which a population is affected. If one considers only the desirable effect of a particular drug, then the importance of the slope lies in its ability to predict the dose of the drug which will produce the desired effect in all or any fraction of the population. The steeper the slope, the narrower the range of doses which encompasses the majority of the population. In the unlikely and "ideal" case where a drug has no undesirable side effects, the ED_{99} (the dose sufficient to be effective in almost all individuals in the population) can be used effectively in virtually all patients. However, for most drugs, as the dose increases, undesirable or side effects become increasingly common. Because at high doses these may include severe toxicity and even death, the safety margin between an effective dose and a toxic or lethal dose is of extreme importance. Therefore, the greater the gap between the effective dose and the dose that causes toxicity or death, the safer the drug. The positioning and slope of the cumulative frequency distribution curves for the desired effect, side effects, toxic effects, and lethal effect are important indicators of the safety of the drug and our ability to use the drug successfully.

The ratio of the drug dose which produces an undesired effect and the dose which causes the desired effects is a *therapeutic index* and indicates the selectivity of the drug and consequently its usability. A single drug can have many therapeutic indices, one for each of its undesirable effects relative to a desired drug action, and one for each of its desired effects if the drug has more than one action. Consequently, a single therapeutic index derived from the ratio of the ED_{50} and the median lethal dose (LD_{50}) values is only a gross assessment of the safety margin. Also, this is likely to be misleading if the dose-response curves from which the values are derived are shallow.

Fig. 2.3 shows two cumulative frequency distribution curves, one for the effective doses of a particular drug and one for the lethal doses. In this hypothetical and extreme case, the effective dose in only 50% of the population (ED_{50}) will cause death in the most-sensitive individual in the population. The dose of the drug sufficient to be effective in almost all the individuals in the population (the ED_{99}) is also the LD_{50} and therefore sufficient to kill half of the population. The margin of safety for this drug is unacceptable.

Fig. 2.4 demonstrates that the slope of the cumulative frequency distribution curve is important in the separation of desirable from undesirable effects. Shown in the figure are the dose-response curves for two drugs (A and B) that have identical ED_{50}'s and identical LD_{50}'s but different slopes to the dose-response curves. To understand the importance of the slope, compare the doses of the two drugs required to produce the desired effect in all members of the population with the range of doses causing death. Drug A, with the steeper dose-response slope, can be used effectively on the whole population without causing death, while drug B, with the shallower curves, cannot be used in this way. The dose of drug B that yields a therapeutic effect in the majority of the patient population will also be lethal to a significant number of patients. Rather than death as the end point for comparing therapeutic cumulative frequency distribution curves, a more clinically meaningful comparison is

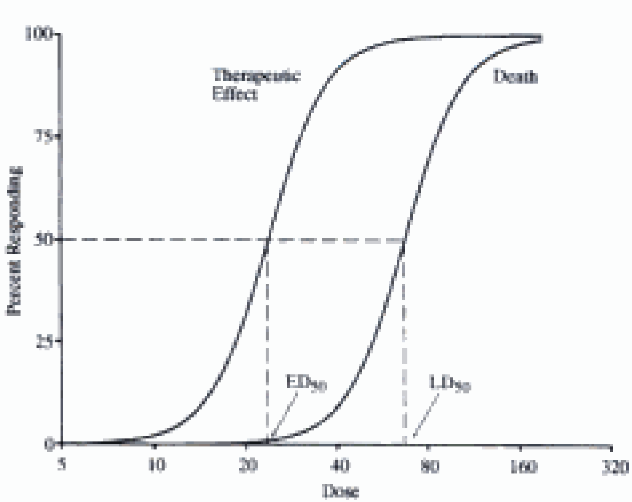

FIG. 2.3

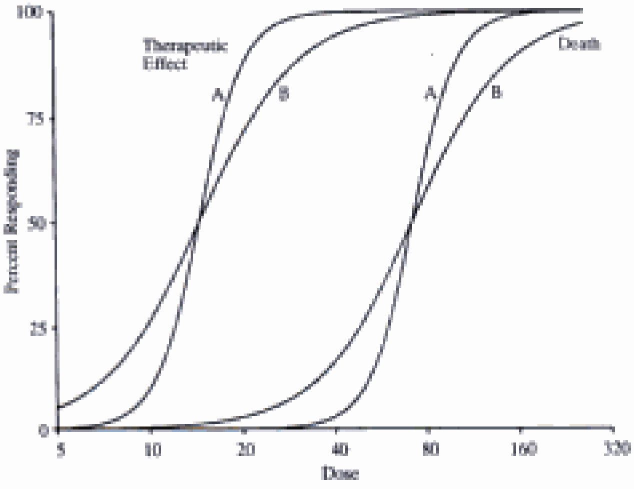

FIG. 2.4

with distribution curves for the relationship between dose and the onset of the manifestations of a drug's toxic principle (e.g., the onset of vomiting, anorexia, or bradycardia for the cardiac glycoside digoxin).

Thus, the use of a drug cannot be predicted on the basis of a therapeutic index derived from the ED_{50}'s and LD_{50}'s alone. A wider knowledge of a drug's properties is required. With respect to effective doses, lethal doses, or doses associated with the onset of toxic drug effects, the important factor is the safety margin and a clear gap between the maximum dose required to produce the therapeutic effect and the minimum dose that will initiate a toxic drug effect or cause death.

QUANTITATIVE ASPECTS OF DRUG-RECEPTOR INTERACTION. The drug concentration in the biophase depends on the amount of drug (dose) administered, route of administration, factors that influence distribution of the drug to the biophase, and the rate of elimination of drug from the biophase and patient. Presence of the drug in the biophase leads to interaction between drug molecules and receptors and thus to a change at the receptor level. The magnitude of this change depends on the concentration of the drug in the biophase, the affinity of the drug for the receptors, and the drug's intrinsic activity. The result of the drug-receptor interaction is the formation of a *stimulus*. The stimulus has a linear relationship to the number of occupied receptors. Action of the stimulus on the effector system results in the quantifiable pharmacologic effect.

Thus, a pharmacologic response is considered to be the result of a reversible interaction of a drug with its receptors. The intensity of response elicited by a drug is a function of the dose administered. In certain instances a drug-receptor response may be characterized as quantal in nature; however, the preponderance of dose-response relationships at the receptor level are better described in terms of a graded response. The drug-receptor-response relationship is summarized in the following equation:

$$\text{drug} + \text{receptor} \leftrightarrow \text{drug-receptor complex} \rightarrow \text{response}$$

The magnitude of response is assumed to be proportional to the number of receptors occupied by the drug, with a maximal response corresponding to occupancy of all receptors. Alternatively, maximal tissue response to a drug may occur when only a fraction of the total number of receptors are occupied by the drug, as previously discussed for the situation when a step subsequent to occupancy of the receptor by the drug is limiting the expression of the drug-receptor response.

Two important assumptions are inherent in the dose-response relationship: (1) the drug response is directly proportional to the percentage of the total number of receptors occupied by the drug and (2) a negligible fraction of the total amount of drug in the body combines with its receptors. The reacting substances are the drug and the unoccupied (free) receptors for the drug:

$$\begin{array}{lcl} \text{drug} + \text{free receptors} & \underset{k_2}{\overset{k_1}{\leftrightarrow}} & \text{drug-receptor complex} \\ (C_x) \quad (100 - Y) & & (Y) \end{array}$$

where C_x is the concentration of the drug in the biophase and Y is the percentage (concentration) of receptors occupied by the drug. Peculiar to this situation is that neither of the reacting substances can be accurately measured, yet conclusions may be deduced from the interaction. At equilibrium,

$$k_1 \cdot C_x(100 - Y) = k_2 \cdot Y$$

Rearranging, $Y/[C_x(100 - Y)] = k_1/k_2 = K_x$, where K_x is the affinity constant of the reaction. The affinity constant is an association constant that relates to the equilibrium attained in the formation of the drug-receptor complex.

Since effective concentration of the drug remains essentially unchanged during the reaction, the ratio of concentration of occupied receptors to that of unoccupied receptors is proportional to the dose administered. That is, the dose that will occupy half of the receptors in the drug-receptor complex gives a 50% response. This will correspond to a situation in which $Y/(100 - Y) = 1$ and $1/ED_{50} = K_x$ so that the median effective dose (ED_{50}) is the reciprocal of the affinity constant of the tissue receptor for the particular drug.

Graphic representation of a graded response with increase in dose has the form of the hyperbola seen previously for quantal dose-response relationships. The response is the dependent variable and the dose is the independent variable. On a semilogarithmic graph, the hyperbola is converted to the familiar sigmoid curve, again analogous to the quantal log dose-response curve. Drugs that produce a particular effect by the same mechanism of action but differ in potency yield a series of parallel log dose-response curves.

DOSE TITRATION STUDIES. An application of the dose-response relationship is in the regulatory approval process for new animal drugs. Traditionally, the dose-response relationship of a new animal drug can be characterized in a manner described above. A clearly defined end point (or end points) of drug efficacy that is related to the proposed clinical indication is evaluated in a population of animals across a range of doses. The critical aspects of the dose-response relationship for the dose or dose range of the drug under study include the lower plateau of the curve at which the dose is ineffective, the slope of the curve, and the upper plateau at which effectiveness is not improved by increasing the dose. When a drug is proposed as being effective over a dose range, efficacy should be demonstrated in such a way that one can determine from the dose-response data that the drug will be effective at all doses within the range. Thus, the lower limit of a dose range may be based, e.g., upon the cumulative frequency distribution curve for the therapeutic effect, whereas the upper limit of a dose range may be based upon some other practical aspect such as safety to the target animal, the potential for drug residues in food products from treated animals, length of withdrawal times for food animals, injection site volume, or development costs pertaining to synthesizing and presenting the drug in its final formulation for the market.

Pharmacokinetics is concerned with study and characterization of the time course of drug absorption, distribution, metabolism, and excretion. Specifically, it is defined as the mathematical description of drug concentration changes in the body. Additionally, it is concerned with the relationship of these processes to intensity and duration of characteristic effects of drugs. An understanding of the dose-effect relationship can generally be obtained by linking pharmacokinetic behavior with information on pharmacodynamic activity (Holford and Sheiner 1981).

The usual reason for administering a drug to an animal is to produce a certain pharmacologic response. This objective may sometimes be achieved, at least in part, by giving a recommended dose of the drug without appreciation of the basis of the recommendation. The most effective use of drugs, based on an understanding of pharmacodynamics and pharmacokinetic principles in the clinical patient, together with some knowledge of product formulations, is the essence of clinical pharmacology. This enlightened approach provides an insight to mechanisms of drug interactions and potential usefulness (or otherwise) of combination preparations.

To produce its characteristic effect(s), a drug must attain effective concentrations at its site of action. In veterinary medicine, this requirement is complicated by the variety of animal species to which therapeutic agents and anesthetics are administered. Wide variations in intensity and duration of pharmacologic effect are commonly observed among species of domestic animals when a drug is given at the same dose level (mg/kg). These variations in response can be attributed to species differences either in the availability of the drug at the site of action or in the inherent sensitivity of tissue receptor sites. Clinical pharmacologic studies suggest that, for the majority of therapeutic agents, the species variations in response are largely due to differences in disposition kinetics of the drugs. This implies that a drug has the same range of therapeutic plasma concentrations, once defined, in the different species. When a drug is administered by the oral route, the rate and extent of its absorption from the gastrointestinal (GI) tract are likely to vary, in particular between monogastric and ruminant animals. Consequently, by influencing the plasma concentrations attained, drug absorption can contribute to species variations in the response to a given dose.

drug influence the concentration attained in the immediate vicinity of its receptor sites, while biotransformation (metabolism) and excretion are responsible for terminating action of the drug. The interrelationship of the various processes that determine duration of drug action is shown in Fig. 3.1. Either directly or indirectly, all these processes involve passage of drugs across membranes. It is important, therefore, to consider briefly the general nature of the biologic membrane and mechanisms by which drugs traverse this cellular barrier.

Nature of Biologic Membranes. Biologic membranes may be viewed as fluid mosaics of functional units composed of lipoprotein complexes (Dowben 1969). The characteristic feature of cell membranes is a bilayer of amphipathic phospholipid molecules, oriented perpendicular to the plane of the membrane, with polar head groups aligned at both surfaces and long hydrocarbon chains extending inward, forming a continuous hydrophobic phase (Benet et al. 1996). Individual lipids can move laterally, endowing the membrane with fluidity, flexibility, imperviousness to polar molecules, and high electrical resistance. The lipid molecules can even flip from one bilayer of the membrane to the other. In this model, proteins integral to the membrane are a heterogeneous set of globular molecules, each arranged in an amphipathic structure, i.e., with their ionic and highly polar groups located largely on membrane surfaces in contact with the extra- and intra-cellular aqueous media and with their nonpolar residues sequestered from contact with water in the membrane interior. These proteins are partially embedded in a discontinuous, fluid bilayer of phospholipids that forms the matrix of the mosaic. Aqueous channels appear to be present in the core of the globular intrinsic (integral) proteins and may be gated (i.e., channels may open and close) by conformational changes in the proteins. Extrinsic proteins are bound to exposed surfaces of the intrinsic proteins by electrostatic or hydrophobic interactions, but they are not involved in lipid-protein interactions critical to the membrane structure and its functions. Cell membranes are approximately 8 nm thick.

Drug Passage across Membranes. Drug molecules move across membranes either by passive transfer or by active participation of the membrane (Benet et al. 1996). In passive transfer, the membrane behaves as an inert lipoid-pore boundary, and drug molecules traverse this barrier either by diffusing through the lipid region or, if of sufficiently small size, by filtering through the postulated aqueous pores (channels). Both nonpolar lipid-soluble compounds and polar water-soluble substances that possess sufficient lipid solubility can cross the predominantly lipoid plasma membrane by passive diffusion. Rate of translocation (diffusion) is directly proportional to concentration gradient across the membrane and lipid-to-water partition coefficient of the drug. Passive diffusion, characterized by movement of drug molecules down a concentration gradient without the cellular expenditure of energy, is by far the most important mechanism for passage of drugs across membranes.

Filtration is a common mechanism for transfer of many small, water-soluble, polar, and nonpolar substances. The apparent diameter of membrane channels differs among various body membranes. Channels in the capillary endothelial membrane are large (4–8 nm depending on capillary location), while those in the intestinal epithelium and most cell membranes are only about 0.4 nm in diameter. Drug permeation through aqueous channels is important in renal excretion (glomerular filtration), removal of drugs from the cerebrospinal fluid (CSF) (arachnoid villi), and passage of drugs across the hepatic sinusoidal membrane.

In terms of drug distribution, penetration into extracellular fluid of the brain and CSF is similar to diffusion into intracellular fluid elsewhere in the body. Capillaries of the brain are unlike the fenestrated (porous) capillaries in muscle and most other tissues; their endothelial cells are joined one to another by continuous tight intercellular junctions. Passage of a drug from cerebral circulation into brain extracellular fluid can take place only by diffusion through capillary endothelial cells (blood-brain barrier). In the choroid plexus, capillary endothelial cells have open intercellular junctions, but choroidal epithelial cells are in close apposition to one another. For a drug to enter CSF from the systemic circulation, it must diffuse through the choroidal epithelial cells (blood-CSF barrier). Likewise, the penetration of drugs into aqueous humor of the eye involves diffusion through the blood-aqueous barrier. The capacity of drugs to penetrate these barriers may be increased in the presence of fever and certain inflammatory conditions.

The pH Partition Hypothesis. Most drugs are weak organic acids or bases and exist in solution as both nonionized and ionized forms. The nonionized form is usually more lipid-soluble and can more readily diffuse across the cell membrane to achieve the same equilibrium concentration on either side. In contrast, the ionized moiety is often virtually excluded from transmembrane diffusion because of its low lipid solubility.

The degree of ionization of an organic electrolyte depends on its pK_a value and the pH of the environment. For an acid this is

$$\%\ \text{ionized} = \frac{100}{1 + \text{antilog}\,(pK_a - pH)} \qquad (3.1)$$

and for a base,

$$\%\ \text{ionized} = \frac{100}{1 + \text{antilog}\,(pH - pK_a)} \qquad (3.2)$$

The pK_a value, the negative logarithm of the acidic ionization (or dissociation) constant, is a constant for an acid or a base. The majority of therapeutic agents have pK_a values between 3 and 11 and exist accordingly as both nonionized and ionized forms within the range of physiologic pH. The ratio of nonionized to ionized drug at a given pH can be calculated from the Henderson-Hasselbalch equation. For an acid this is

$$pH - pK_a = \log \frac{(\text{conc. ionized})}{(\text{conc. nonionized})} \qquad (3.3)$$

and for a base,

$$pH - pK_a = \log \frac{(\text{conc. nonionized})}{(\text{conc. ionized})} \qquad (3.4)$$

From Eqs. 3.3 and 3.4 it is apparent that when pH and pK_a values are equal, 50% of the drug exists in either form. When the pH is one unit below the pK_a, an acid is 9% ionized and a base, 91%. In the case of an acid (vice versa for a base), each one pH unit change to the acid side of the pK_a results in a tenfold increase in nonionized form relative to ionized form; the converse occurs when shifts to the alkaline side of the pK_a are made. Because of the relationship between pH and degree of ionization, a relatively small pH change will produce a large change in the proportion of drug present in nonionized form, particularly when the pH of the solution is numerically close to the pK_a of the weak organic electrolyte.

Distribution of a weak electrolyte is usually determined by its pK_a value and pH gradient across the membrane. The nonionized moiety diffuses across the membrane at a rate determined by its lipid solubility. Because of the pH difference on either side of the membrane, the degree of ionization will differ. At equilibrium, there will be a higher total (nonionized plus ionized) concentration of drug on the side of the membrane where the degree of ionization is greater. This phenomenon is known as the ion-trapping mechanism. To illustrate the effect of pH on distribution of drugs, partitioning of a weak organic acid (pK_a 4.4) between plasma (pH 7.4) and gastric juice (pH 1.4) is depicted in Fig. 3.2. It is assumed that the gastric mucosal membrane behaves as a simple lipoidal barrier permeable only to the lipid-soluble, nonionized form of the acid. At equilibrium, the total drug concentration ratio between plasma and gastric juice would be approximately 1000:1. Accordingly, weak organic acids such as aspirin (pK_a 3.5), phenylbutazone (pK_a 4.4), sulfadiazine (pK_a 6.4), and phenobarbital (pK_a 7.4) are well absorbed from the GI tract of dogs and cats. Likewise, the acidic urinary reaction of the carnivorous species promotes passive reabsorption of acidic drugs (pK_a values between 3.0 and 7.2) from the distal portion of the nephron. Conversely, urinary alkalinization will

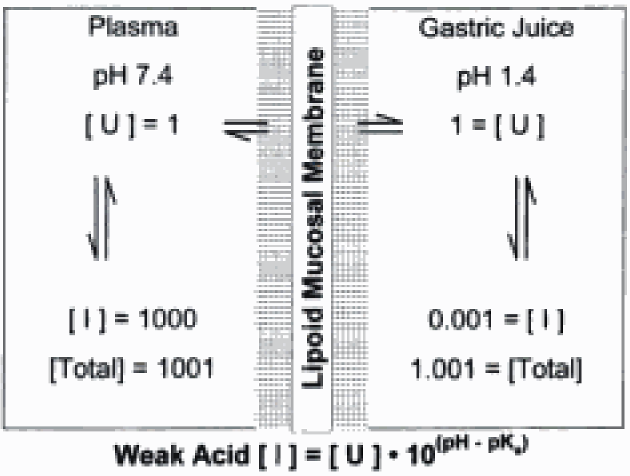

FIG. 3.2—Effect of pH gradient on distribution of a weak organic acid (pK_a 4.4) between blood plasma (pH 7.4) and gastric juice (pH 1.4). In this figure, [I] and [U] represent the concentrations of the ionized and nonionized fractions of the drug, respectively. A dynamic equilibrium exists between ionized and nonionized drug.

promote their excretion by favoring ionization of organic acids. Although the excretion rate of several drugs may be altered by changing urinary pH, this technique will have little clinical application in management of overdosage unless a significant fraction of the dose is excreted unchanged (unmetabolized) as the parent drug in the urine. It may be significant that weak organic bases (alkaloidal substances), tetracyclines, and macrolide antibiotics, administered parenterally, diffuse passively into the rumen of cattle and sheep and into the colon of horses as part of their usual distribution pattern. At these important sites of microbial digestion, those drugs may interfere with functioning of microorganisms or be inactivated by them. Basic drugs (narcotic analgesics, phenothiazine tranquilizers, ketamine, xylazine, diazepam, antiarrhythmic agents) tend to concentrate in fluids that are acidic relative to plasma, such as intracellular fluid (pH 7.0).

The theoretical equilibrium concentration ratio ($R_{x/y}$) of a drug on opposite sides of a biologic membrane may be calculated according to the following equations (Jacobs 1940). For an acid this is

$$R_{x/y} = \frac{1 + 10^{(\mathrm{pH}_x - \mathrm{pK}_a)}}{1 + 10^{(\mathrm{pH}_y - \mathrm{pK}_a)}} \tag{3.5}$$

i.e.,

$$R_{x/y} = \frac{1 + \text{antilog}\,(\mathrm{pH}_x - \mathrm{pK}_a)}{1 + \text{antilog}\,(\mathrm{pH}_y - \mathrm{pK}_a)} \tag{3.6}$$

and for a base,

$$R_{x/y} = \frac{1 + 10^{(\mathrm{pK}_a - \mathrm{pH}_x)}}{1 + 10^{(\mathrm{pK}_a - \mathrm{pH}_y)}} \tag{3.7}$$

The validity of these equations for predicting passage of antimicrobial agents from the systemic circulation into the milk of lactating animals is well documented (Table 3.1). It has been shown that only the lipid-soluble nonionized moiety of an organic electrolyte in the water phase of blood plasma diffuses into milk (Rasmussen 1966). This indicates that the mammary gland epithelium behaves as a lipoidal membrane that separates blood of pH 7.4 from milk, which has a somewhat lower pH value (normal range is 6.5–6.8). In normal lactating cows, weak acids give milk ultrafiltrate to plasma ultrafiltrate concentration ratios less than or equal to unity; organic bases, excluding aminoglycoside antibiotics (which are polar in nature), attain concentration ratios greater than one. In mastitis, the milk pH reaction may be increased up to 0.7 of a pH unit, so higher concentration ratios than those in normal animals will be obtained for the organic acids (Ziv et al. 1983). Choice of antimicrobial agent for systemic therapy of mastitis should be based upon susceptibility of the infecting microorganism to the drug and upon the active drug concentration that can be attained in the milk with usual dosage. The former can be determined in vitro, and the latter may be predicted by Eq. 3.5 or 3.7.

Carrier-Mediated Transport. Carrier-mediated transport across membranes implies a rapidly reversible interaction between components of the membrane and the transported substance. This kind of transport shows relative selectivity toward the chemical nature of the substance moved across the membrane. Since a carrier (membrane component) is involved in transport, the process is saturable, and substances of a similar chemical nature may compete for the carrier. Competitive inhibition is a characteristic of carrier-mediated transport.

Active transport and facilitated diffusion are both carrier-mediated processes but differ in that the former requires direct expenditure of energy. The rapid transfer into urine and bile of drugs that are strongly acidic or basic as well as most drug metabolites takes place by active transport. It is also responsible for removal of certain drugs (e.g., penicillins) from the central nervous system (CNS) at the choroid plexus. This is now believed to be accomplished through reverse transport from the CSF back into the bloodstream by the *p*-glycoprotein pump (Miyama et al. 1998). Generation of the pH gradient across a biologic membrane is an active process.

Facilitated diffusion is neither an energy-dependent process nor does it move substances against a concentration gradient. Transport is facilitated, however, by attachment to a carrier and is more rapid than simple diffusion. Entry of glucose into most cells takes place by facilitated diffusion (enhanced by insulin), but its passage across the GI mucosa and excretion by proximal renal tubular cells are active processes.

Most inorganic ions are sufficiently small to penetrate membranes pores, but their concentration gradient across the cell membrane is generally determined by the transmembrane potential (e.g., chloride ion) or by active transport (e.g., sodium and potassium ions). The

TABLE 3.1—Passage of antimicrobial agents from the systemic circulation into milk

			Concentration ratio (milk ultrafiltrate:plasma ultrafiltrate)		
Drug	pK_a	Milk pH	Theoretical	Experimental	Reference
Organic acids

Note: Individual references should be consulted for the design of each experiment. It is important to know the method of drug administration, since equilibrium will not be established after a single IV injection.

potassium-sustaining diuretic agents appear to inhibit sodium-potassium exchange mechanisms in the distal nephron (specifically, the cortical collecting tubules) either by competitively antagonizing tubular action of aldosterone (e.g., spironolactone) or by interfering directly with tubular transport of these cations (triamterene, amiloride).

DRUG ADMINISTRATION. For a drug to act and produce its characteristic systemic effects, it must first be absorbed and then attain an effective concentration at its site of action. Drug absorption is generally defined as passage of the drug from its site of administration into the bloodstream. Drugs are administered in prepared dosage forms called drug products rather than as raw drug substances. The drug product contains a certain amount of the pharmacologically active drug substance(s) incorporated into a dosage form. The dosage form and route of administration can influence the selectivity of a drug product and thereby its clinical indications. The absorption process is governed by solubility of the dosage form, route of administration, and certain physicochemical properties of the drug substance. A balance is needed between water solubility (necessary for the drug to dissolve in the intestinal fluid and for distribution in the extracellular fluids of the body) and the lipid solubility required to enhance membrane transit across the GI tract as well as other membranes in the body.

A drug can be given either orally (by mouth) or by a parenteral route when systemic effects are desired. Parenteral administration indicates that the GI tract is bypassed and the drug is given by injection or inhalation (as in the case of inhalant anesthetics). Topical application and intramammary and intrauterine infusions are employed when local effects are sought. A variable degree of drug absorption takes place from these sites of administration, the extent of which depends largely on the formulation of the preparation administered and also on the drug itself.

Parenteral Administration. The major routes of parenteral administration are intravenous (IV), intramuscular (IM), and subcutaneous (SC). Other parenteral routes include tissue infiltration and intra-articular, subconjunctival, and epidural injections, which are used when localized action is sought. Parenteral injection necessitates that strict asepsis be maintained to avoid infection.

IV Injection. Injection of a drug solution directly into the bloodstream gives a more predictable concentration of the drug in plasma and produces immediate plasma concentrations which can produce a pharmacologic response. This is true because the entire dose of the drug is administered directly into the systemic bloodstream rather than being administered extravascularly and requiring the drug to be absorbed from the injection site into the systemic circulation. Another advantage of the intravascular route is that, by controlling the infusion rate, the veterinarian can control the rate of introduction of a drug into systemic circulation, and hence the effects may be immediately titrated (i.e., administering a drug to effect). IV injection should be performed slowly, except in special circumstances. Induction of anesthesia by rapid introduction into the bloodstream of a small dose of thiopental (thiobarbiturate) as an IV bolus is a special application of IV drug administration. Rapid penetration of the blood-brain and blood-CSF barriers by this lipophilic thiobarbiturate allows an almost immediate onset of anesthesia.

The duration of anesthetic effect is related mainly to redistribution of the drug from highly perfused CNS and visceral organs to the less well perfused muscle and other tissues. In some instances, as in induction of surgical anesthesia with pentobarbital in dogs and small ruminant species, the exact dose is not predetermined but the amount of drug administered is determined by the response of the animal. Certain irritating and hypertonic solutions can be given only by the IV route. One must ensure that the tip of the needle is in the lumen of the vein, so that the drug solution can be injected freely without causing either intimal or perivascular damage. Drugs in an oily vehicle or drug suspensions should not be given by the IV route.

Continuous IV infusion is an effective technique for achieving and maintaining steady-state concentration of a drug. A particular infusion rate is determined simply by fixing the rate of flow and concentration of drug in the infusion solution. While the rate of infusion determines the steady-state concentration achieved, time taken to reach the steady state is determined solely by the value of the overall elimination half-life of the drug (see the section below on quantitating drug elimination). The more rapidly a drug is eliminated (i.e., the shorter the half-life of the drug), the shorter the time required to achieve a steady state. To immediately establish the desired concentration, the classic procedure is to administer a loading dose as an IV bolus and at the same time start infusing the drug at a constant rate.

Although the IV route has many advantages, it is potentially the most dangerous route of drug administration. Great care must be exercised in computing the total dose to be administered (this applies to all parenteral routes) and rate of injection. Furthermore, rapid IV injection will result in transiently high concentrations in the bloodstream, and hence other tissues, enhancing the likelihood of acute toxicities (among the most important of which are CNS toxicities).

Extravascular Administration. Absorption of most drugs from IM and SC injection sites is rapid when given as aqueous solutions; the peak concentration in plasma is usually attained within 30 minutes. The rate of drug absorption is determined mainly by the vascularity of the injection site. However, other factors that affect the rate of drug absorption include the drug concentration in parenteral solution, the degree of ionization and lipid solubility of the nonionized form, and area of the absorbing surface to which the drug is exposed. Differences in drug absorption may exist not only between IM and SC injection sites but also between various IM locations. As an example, absorption of atropine, scopolamine, and glycopyrrolate was more rapid when administered IM to humans in the deltoid muscle compared with the gluteal region (Ali-Melkkila et al. 1993). A drug may influence its own rate of absorption and uptake of another drug administered simultaneously if it alters the blood supply or capillary permeability at the injection site. Addition of epinephrine, usually to give a final concentration of 1:100,000, to solutions of local anesthetics (procaine, lidocaine) is a good example. By causing local vasoconstriction (α-adrenoceptor activation), it delays absorption of the local anesthetic and thereby prolongs duration of analgesia, decreases the amount of anesthetic required, and lessens the danger of systemic toxicity.

The assumption that drugs are completely available systemically from all parenteral products injected intramuscularly is invalid, as shown for diazepam (Gamble et al. 1973), digoxin (Greenblatt et al. 1973), and florfenicol (Lobell et al. 1994; Soback et al. 1995). Incomplete availability may be attributed to low solubility of a drug at the pH of the tissue or to a damaging effect caused by the preparation at the injection site. Certain parenteral preparations (droperidol-fentanyl, ketamine) cause pain when injected intramuscularly, which can only be attributed to their formulation.

Sustained-release preparations, mostly of antimicrobial agents, are designed to give long duration of therapeutically effective plasma drug concentrations, e.g., procaine penicillin G (buffered aqueous suspension or in oil containing aluminum monostearate), amoxicillin trihydrate (aqueous suspension), oxytetracycline base in 2-pyrrolidone, and tilmicosin phosphate. The prolonged action provided by these preparations is due to their limited rate of absorption, which may be attributed to slow dissolution and/or absorption of the drugs. Formulation of sustained-release preparations must be such that their IM injection will not cause significant tissue damage with residual levels persisting at the site of administration at the time the food-producing animals go to slaughter (Nouws et al. 1990). The main disadvantages are loss of flexibility in dosage, but this is often offset by the tremendous added convenience of these products for the practicing food-animal veterinarian and by the reduction in animal stress associated with repeated capture and restraint.

Extremely slow absorption can be achieved by incorporating an insoluble drug into a compressed pellet or polymer suitable for SC implantation. Several steroid hormones (desoxycorticosterone acetate, trenbolone acetate, testosterone) are effectively administered in this manner. This is the basis for hormonal implants placed in the ear of feedlot cattle to improve feed efficiency and promote weight gain.

Percutaneous Absorption. The ability of a drug, applied topically as a dermatologic preparation, to be absorbed through the skin depends on three consecutive events. It must first dissolve and be released from the vehicle, then penetrate the keratin layer (stratum corneum) and cells of the epidermis, and finally be taken up by the capillary blood supply. Since absorption takes place by passive diffusion, lipid solubility is the most important physicochemical property of the drug. Concentration of a drug in its formulation is an obvious factor influencing its absorption. In terms of the vehicle, drug absorption is enhanced from an oil in water emulsion base, e.g., aqueous cream, which contains the anionic surface-active agent sodium lauryl sulfate. Surfactants increase skin penetration of water-soluble substances, possibly by increasing the permeability of the skin to water. Dimethyl sulfoxide, a skin irritant in humans, is a sorption promoter that passes rapidly through the stratum corneum (Ponec et al. 1990; Sodicoff et al. 1990) and has been found to accelerate penetration through the skin of water, fluocinolone acetonide, salicylic acid, and other substances. The percutaneous absorption of corticosteroids is also increased by so-called occlusive dressings (e.g., polyethylene). Since the stratum corneum is the barrier to skin penetration, presence of a de-epithelialized surface permits absorption of substances that are poorly absorbed through intact skin. Toxic effects may sometimes follow percutaneous absorption of lipid-soluble substances such as pesticides in an organic solvent.

When a skin infection is located in the deeper layers of the epidermis or in the dermis, systemic therapy with an antibacterial or antifungal agent is often more effective than topical application. Based on culture and sensitivity alone amoxicillin is often the antibiotic considered first for such infections, but it is worth considering other agents with good tissue-penetrating capacity (clindamycin, erythromycin, lincomycin, trimethoprim/sulfadiazine) for treatment of deep-seated or persistent dermatoses. Mycotic disease of the skin, hair, claws, and nails caused specifically by *Microsporum*, *Epidermophyton*, or *Trichophyton* species responds well to oral dosage with griseofulvin (using micronized preparations), provided the drug is given for an adequate time.

Agents that are primarily used topically for their local action are discussed elsewhere in this text.

Pulmonary Absorption. Gaseous and volatile liquid anesthetic agents, given by inhalation, are rapidly absorbed into the systemic circulation by diffusing across the pulmonary alveolar epithelium. Inhalant anesthetics are highly soluble in lipids but differ widely in their blood solubility (blood/gas partition coefficient) and blood/brain partitioning. These properties determine the rate of induction, ease with which level or depth of anesthesia can be changed, and speed of recovery. With agents of high blood solubility (halothane, methoxyflurane) these processes, like the equilibration in body water, take place slowly. The converse situation holds true for an agent of very low blood solubility (nitrous oxide). Blood solubility of an inhalant anesthetic also determines the extent to which the physiologic parameters of pulmonary ventilation (high-solubility agents) and cardiac output (low-solubility agents) influence rates of induction and recovery in clinical anesthesia. Both physiologic parameters influence the induction of and recovery from halothane anesthesia, which has an intermediate blood solubility.

Drug Administration by the Oral Route. Although some oral solutions, either aqueous or elixirs, and suspensions are available commercially, most oral dosage forms are solids and include the tablet, bolus for large animals, pellet, capsule, and a variety of specialized sustained-release products for ruminants.

Before entering the systemic circulation, a drug administered as a solid dosage form must undergo three events: release from the dosage form, diffusion and/or transport across the GI mucosal barrier into the portal circulation, and passage through the liver (Fig. 3.3). Each of these events has the potential to decrease the amount of drug reaching the systemic circulation intact (unchanged); the net effect is reflected in the bioavailability profile.

Dissolution is the rate-limiting step that determines release of drug from a solid dosage form, and it frequently controls the rate of drug absorption. The dissolution process can be enhanced by administering the drug in salt form (phenytoin sodium, propranolol hydrochloride) or by decreasing the particle size, oftentimes using a technique called micronization (griseofulvin, spironolactone). Following its dissolution, the drug in solution must be stable in the environment within the stomach (reticulorumen) and small intestine and must be sufficiently lipid-soluble to diffuse through the mucosal barrier to enter the hepatic portal venous blood. A drug that is stable (neither chemically nor enzymatically inactivated) in GI fluids, with a sufficient degree of both water solubility and lipid-solubility, would be expected to be well absorbed. Penicillin V potassium, which is the potassium salt of the phenoxymethyl analog of penicillin G, is more stable in an acidic medium than the latter; therefore, a greater fraction of the dose should be available for absorption. In small animals, amoxicillin has far greater systemic availability (60–70%) than ampicillin (20–40%). To increase the systemic availability of ampicillin, the prodrug hetacillin (which is rapidly hydrolyzed to ampicillin in the bloodstream) was developed. Cephalexin is an acid-stable cephalosporin that, in contrast to cefazolin and cephalothin (parenteral cephalosporins), is well absorbed from the GI tract. This antibiotic is available as the monohydrate in several oral dosage forms. Erythromycin, administered as the acid-resistant estolate ester, is well absorbed from the small intestine. Oral preparations of all the tetracyclines are available, mostly as the hydrochloride salts. These antibiotics are adequately although incompletely absorbed and, because of their tendency to cause GI disturbances, should not be given to a fasting animal. Milk or milk products and antacids, however, impair absorption of tetracyclines. This interaction may be attributed to chelation or an increase in gastric pH. Systemic sulfonamides (sulfamethazine; sulfadiazine sulfamethoxazole and sulfadoxine, which are combined with trimethoprim) are well absorbed, whereas the enteric sulfonamide succinylsulfathiazole is poorly absorbed. The aminoglycoside antibiotics (neomycin, streptomycin, kanamycin, gentamicin), because of their low solubility in lipid, are poorly absorbed from the GI tract. As a consequence, administration of these polar antibiotics by the oral route should not even be considered in

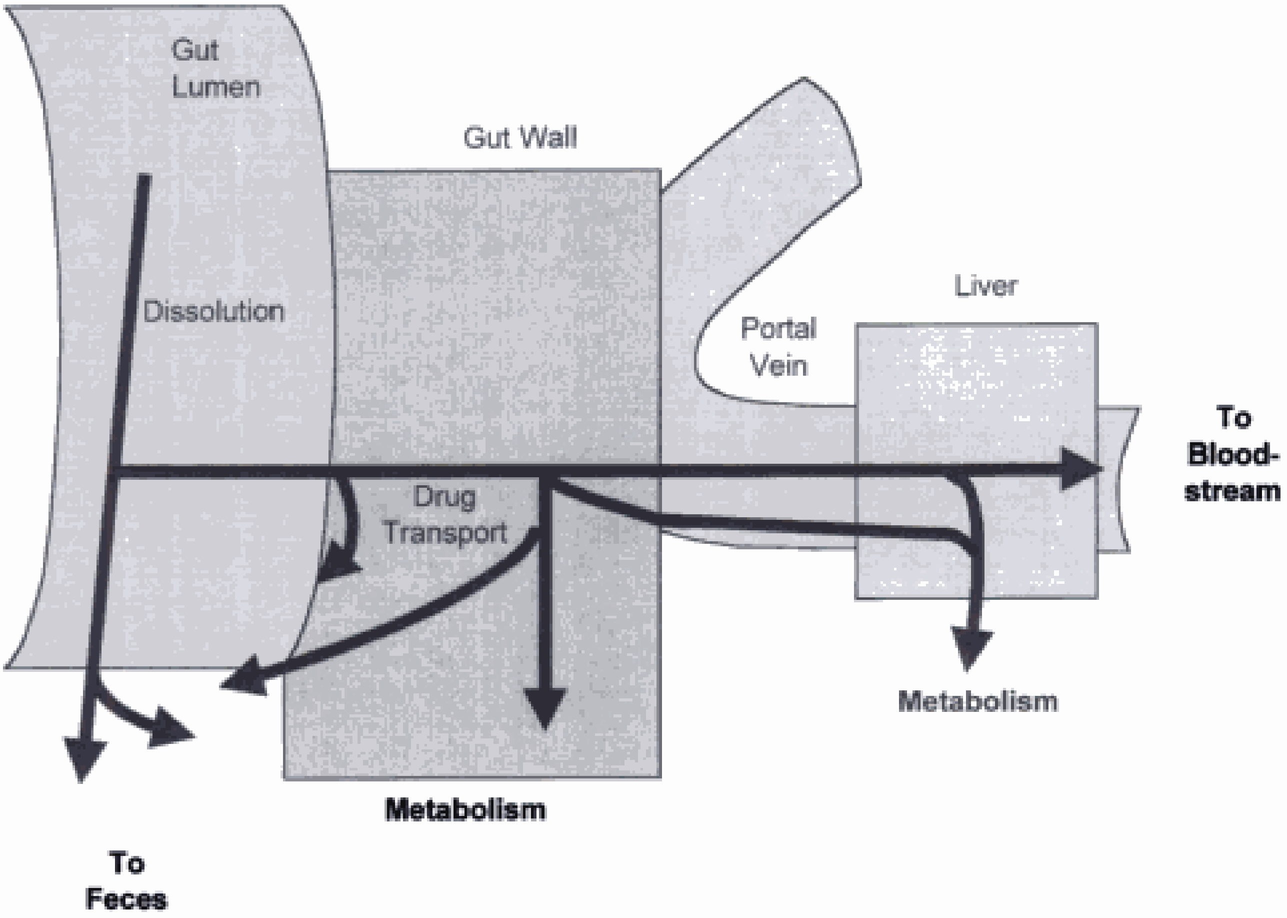

FIG. 3.3—A drug, given as a solid, encounters several barriers and sites of loss in its sequential movement during gastrointestinal absorption. Dissolution, a prerequisite to movement across the gut wall, is the first step. Incomplete dissolution or metabolism in the gut lumen or by enzymes in the gut wall is a cause of poor bioavailability. Removal of drug as it first passes through the liver further reduces bioavailability.

treatment of systemic and urinary tract infections. They are completely available systemically from parenteral preparations injected intramuscularly or subcutaneously.

Because of the extensive surface area and rich blood supply of its mucosal surface, the small intestine is the principal site of absorption for all drugs given orally, regardless of whether they are weak acids, weak bases, or neutral compounds. The rate of gastric emptying is therefore an important determinant of drug absorption. Gastric emptying depends on various physiologic factors such as autonomic and hormonal activity as well as the volume and composition of gastric contents. A change in gastric emptying or intestinal motility is of most importance with poorly soluble drugs and enteric-coated or slow-release formulations.

An effective pH of 5.3 in the microenvironment at the mucosal surface of the intestinal epithelial barrier, rather than the pH of intestinal contents (pH 6.6), is consistent with observations on the absorption of organic electrolytes. It has been shown that in the normal intestine, weak acids with pK_a values above 3 and bases with pK_a less than 7.8 are very well absorbed (Hogben et al. 1959). Changes in the intestinal blood flow will alter the rate of absorption of lipid-soluble drugs (Ther and Winne 1971; Rowland et al. 1973). Absorption of quaternary ammonium compounds such as the antimuscarinic agents propantheline and methscopolamine is slow and incomplete, which may explain their relatively selective antispasmodic effect. Absorption of loperamide is also minimal, relegating its opiate receptor actions to its local effects on intestinal motility.

Recent observations of relatively low oral absorption for compounds with physicochemical properties lending themselves to absorption across biological membranes (e.g., cyclosporine) have led to the discovery of a tandem system of a reverse transport system and metabolizing enzymes in the intestinal mucosa that significantly reduce oral absorption of such compounds. The substrate specificity for the *p*-glycoprotein pump (also known as the multiple drug resistance protein), oriented to pump drugs from the mucosa into the intestinal lumen, and that for the cytochrome P-450 isoenzyme found in the intestinal mucosa work in unison to significantly impair absorption of several therapeutic compounds (Zhang et al. 1998). The significance of this system is only now being elucidated.

Comparative Aspects of Drug Absorption. The pH gradients between plasma and GI fluids of various species play an important role in determining the extent of absorption of orally given drug products and the degree of distribution or excretion into the GI tract of parenterally administered drugs that are weak organic electrolytes. These gradients differ in different domesticated species and are largely dependent on dietary habits.

Domestic animals may be divided on the basis of dietary habit into herbivorous (horse, cow, sheep, goat, chicken, turkey), omnivorous (pig), and carnivorous (dog, cat) species. The physiology of digestion and drug absorption is, in general, similar in the pig, dog, and cat and not unlike that in humans. The rate of gastric emptying is probably the most important physiologic factor controlling drug absorption rate, since the small intestine is the principal site of absorption. Precise information on the physiologic factors that control absorption of drugs in horses is lacking. The horse is a continuous feeder and its stomach, which has a relatively small capacity, is seldom empty. The mean pH of gastric contents is usually higher in the horse (pH 5.5) than in the dog and pig (usual pH range is 3–4). However, unlike most species, neither the dog nor the cat are basal acid secretors; rather, their gastric pH varies from 1 to 6 based on the temporal relationship to feeding stimuli (Gupta and Robinson 1988). For this reason, dissolution of some types of formulations (i.e., those dependent upon an acidic environment for dissolution) may be drastically different in fasted dogs and cats compared with those administered the drug postprandially. Absorption of some drugs (e.g., phenylbutazone) administered orally to horses after feeding takes place mainly in the large intestine. The microbial digestion of polysaccharides, which takes place in the colon, is an essential digestive process in the horse. Disturbance of the microorganisms indigenous to this region of the digestive tract, resulting from either disease or antimicrobial therapy, can have serious consequences.

The principal feature of digestive physiology in the ruminant animal is that microbial fermentation takes place continuously in the reticulorumen. The forestomach contents vary from fluid to semisolid consistency, and the pH reaction is normally maintained within a relatively narrow range (pH 5.5–6.5) in spite of the high concentrations of volatile fatty acid produced. This is accomplished by buffers secreted in alkaline saliva (pH 8.0–8.4) and, it appears, directly by the forestomach epithelium. Despite the stratified squamous nature of its epithelial lining, the rumen has been shown to have considerable absorptive capacity (Phillipson and McAnally 1942; Masson and Phillipson 1951). After comminution by both microbial digestion and rechewing, the liquid portion of reticuloruminal contents, in which small particles of feed are suspended, is pumped by the omasum into the abomasum. Based on average values of salivary flow and volume of the rumen liquid pool (60 L in cattle, 4.5 L in sheep), the turnover rate for reticuloruminal fluid is estimated to be 2.0/day for cattle and 1.1–2.2/day for sheep (Hungate 1966). Reaction of abomasal contents does not vary much and is usually about pH 3 (Masson and Phillipson 1952).

Due to the large volume of ruminal fluid, a drug can attain only a relatively low concentration in this organ, whether it is given in solution or as a solid dosage form. This diluting effect may deter rate but not necessarily extent of absorption. The nonionized, lipid-soluble form of weak organic acids in particular should normally be well absorbed from the rumen. Indigenous microflora may inactivate certain drugs by metabolic transformations of a hydrolytic or reductive nature. Chronic oral dosage with an antimicrobial agent can suppress microflora activity and thereby disturb carbohydrate digestion, which is an essential function of the forestomach. Lipid-soluble, parenterally administered organic bases diffuse from the systemic circulation into ruminal fluid, in which they may become trapped by ionization, depending on their pK_a values. At pH reactions below the pK_a, acids exist mainly in the nonionized form, whereas bases are predominantly ionized. The concentration of a weak organic electrolyte in ruminal fluid is influenced by the dose administered, route of administration, lipid solubility and pK_a of the drug, relative rates of uptake from and passage into the ruminal fluid (both of which take place by nonionic diffusion), rate of salivary flow (for organic acids), extent of drug binding to plasma proteins, and efficiency of elimination (biotransformation and excretion) processes.

Quantitating Drug Absorption. The processes of absorption, distribution, metabolism, and excretion are often quantitated retrospectively so that dosage regimens that target therapeutic concentrations can be prospectively predicted. Quantitation of drug absorption includes both a rate component and an extent component.

One of the fundamental approaches is to quantitatively describe the plasma drug concentrations observed over time after one or more administered doses of a formulation. Mathematical or empirical curves can be fitted to the plasma concentrations over time. From those graphical representations of drug disposition over time, several useful parameters can be calculated. One of the most fundamental parameters is the area under the plasma concentration versus time curve (AUC), which is proportional to the systemic exposure to a drug. Graphically, plasma concentration is plotted on the Y-axis, and time is plotted on the X-axis (Fig. 3.4). The AUC may be calculated by the trapezoidal rule, with extrapolation to infinite time (Baggot 1977). By itself, the AUC has little relevance. However, the AUC can be used in the calculation of several more physiologically meaningful pharmacokinetic terms.

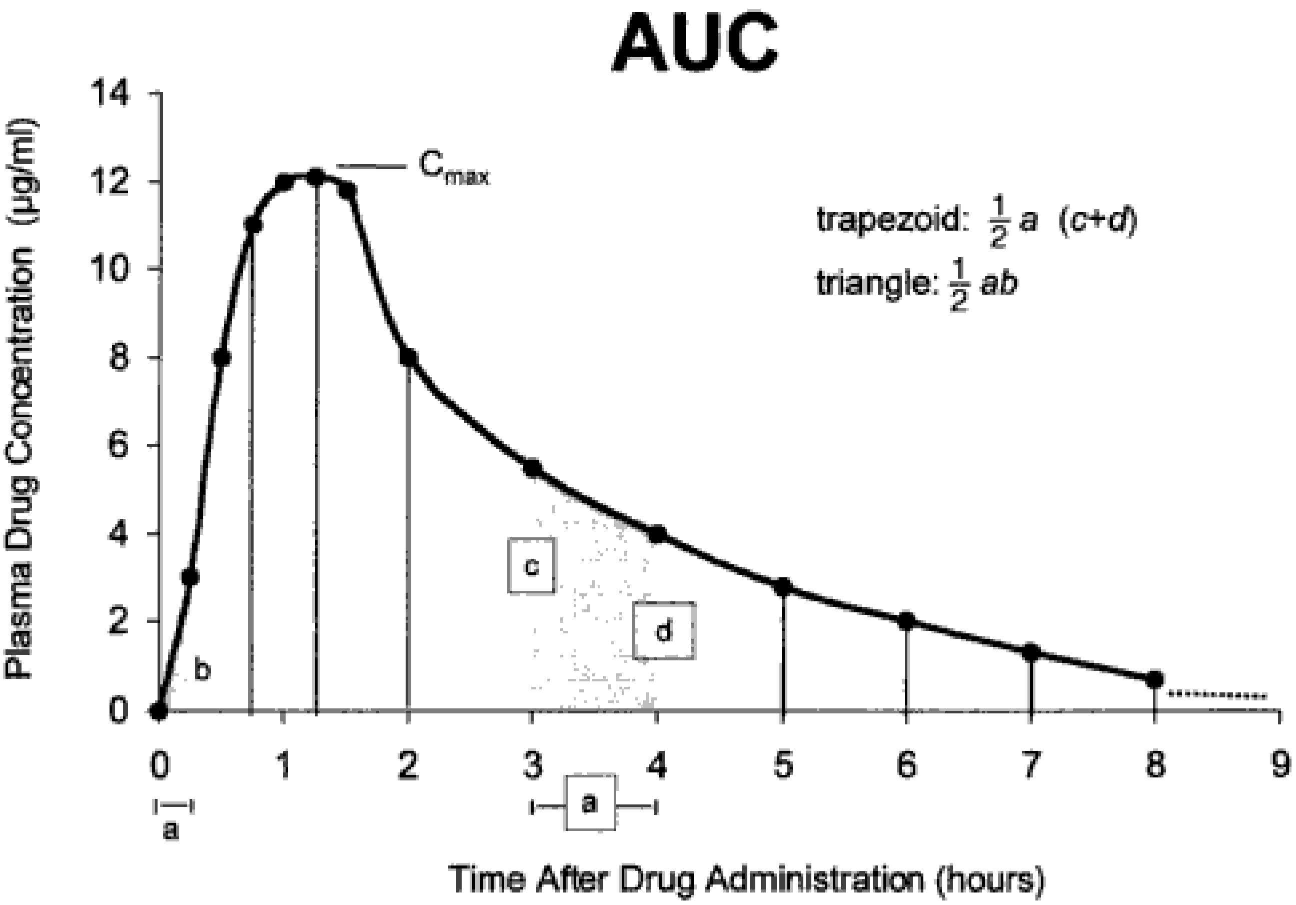

FIG. 3.4—The area under the concentration–time curve (AUC)is estimated by the sum of all the trapezoids and triangles bounded by the curve and is mathematically calculated as the integral of the curve.

A related term necessary for further calculations is the area under the first statistical moment curve (AUMC). This is defined as the area under the (plasma drug concentration · time) versus time curve. The Y-axis in this case is the product of the observed plasma concentration and the time after dosing that the plasma concentration was observed, whereas the X-axis is simply time after drug administration (Fig. 3.5).

RATE OF ABSORPTION. An estimate of absorption rate of a drug from a particular dosage form is given by the time at which the peak is reached on the plasma concentration versus time curve. Remember, however, that absorption continues after peak concentration has been reached. Alternatively, rate of absorption can be characterized by the half-life of absorption, which is the time it takes for half of the drug waiting to be absorbed reaches the systemic circulation.

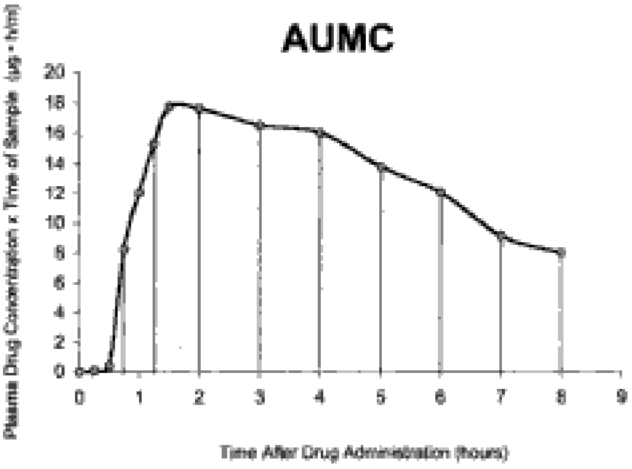

FIG. 3.5—The area under the moment curve is the integral of the curve plotting the product of concentration and time by the time the concentration was observed.

EXTENT OF ABSORPTION. Bioavailability is defined as the extent to which a drug administered as a particular dosage form enters the systemic circulation intact. This pharmacokinetic parameter is but the first of many factors determining the relationship between drug dosage and intensity of action. The usual technique for estimating the systemic availability (*F*) or extent of absorption of the drug employs the method of corresponding areas, which entails comparison of the total AUC obtained after administration via the oral or other nonvascular route with the AUC observed after IV administration of equal doses of

TABLE 3.2—Systemic availability of some drugs given orally to dogs

Drug (dosage form)	Dose	Systemic availability	Contributing factor(s)	Reference
	(mg/kg)	*(%)*		
Digoxin (tablet)	1 mg (total)	80	Dissolution	De Rick et al. 1979
Propranolol (tablet)	80 mg (total)	2–7	Hepatic metabolism	Kates et al. 1979
Lidocaine (solution)	10	15	Hepatic metabolism	Gugler et al. 1975
Salicylamide (solution)	30	22	Metabolism (intestinal wall and the liver)	Gugler et al. 1975
Levodopa (solid in gelatin capsules)	25	44	Metabolism (gastrointestinal lumen and/or intestinal wall)	Cotler et al. 1976
Sulfadimethoxine (suspension)	55	50	(Dissolution and hepatic metabolism?)	Baggot et al. 1976; Sams and Baggot 1977

the drug (in appropriate dosage forms) to the same animals:

$$F = \mathrm{AUC}_{oral}/\mathrm{AUC}_{IV} \qquad (3.8)$$

By definition, IV injection of a drug substance represents complete systemic availability. If an IV preparation of the drug is not available, a reference formulation and route of administration (usually a well-established aqueous solution or elixir) may be used for comparison, in which case the relative bioavailability rather than absolute bioavailability is measured.

When the systemic availability of a drug is incomplete, the ratio of the areas (Eq. 3.8) at equal doses is less than 1.0 (or 100%). This situation could arise for a variety of reasons that may be physicochemical and/or physiologic in nature. They include poor dissolution of the drug product (solid dosage form) in GI fluids, instability or inactivation of the drug substance in luminal contents, poor passage through the mucosal (epithelial) barrier, and metabolism in either the intestinal mucosa or liver preceding entry of the drug into the systemic circulation (first-pass effect). Incomplete systemic availability of a drug due to first-pass effect could be misinterpreted as defective absorption. The systemic availability of some drugs from oral preparations administered to dogs is shown in Table 3.2.

High clearance by the liver is a characteristic of drugs that show a significant first-pass effect (lidocaine, propranolol, diazepam). Phenytoin has a short half-life and is poorly available systemically in dogs (Sanders and Yeary 1978). Wide variation in the bioavailability profile occurs among individual dogs given a single dose (30 mg/kg) of phenytoin in capsules. Time taken to reach the peak serum phenytoin concentration varies from 2 to 12 hours, and the peak concentration ranges from 2.66 to 7.90 g/mL. Appearance in the serum of a metabolite in large amounts indicates that the liver may be largely responsible for reducing systemic availability of phenytoin.

Species Variations in Bioavailability. Considerable variations in bioavailability of drugs from oral dosage forms are likely to exist, particularly between monogastric and ruminant species. When chloramphenicol is given orally (capsules) at the same dose (22 mg/kg) to ponies, goats, pigs, dogs, and cats, areas under the plasma concentration-time curves vary widely (Fig. 3.6). Based on the relative areas, the extent of chloramphenicol absorption is greatest in cats and decreases in the following order: cats, dogs and swine (approximately similar areas), ponies, goats. In goats, the antibiotic is rapidly inactivated by reduction of the aromatic nitro group to an arylamine by rumen microflora (Theodorides et al. 1968; De Corte-Baeten and Debackere 1978); consequently, chloramphenicol is not even available for absorption.

Interspecies variation became evident in a comparative study of salicylate ($\mathrm{pK_a}$ 3.0) absorption in which sodium salicylate contained in gelatin capsules was administered orally at three dose levels (18.5, 50, and 133 mg/kg) to dogs, swine, ponies, and goats (Davis and Westfall 1972). Inspection of the plasma salicylate concentration-time curves (Fig. 3.7) shows that a considerably larger amount of salicylate is available systemically in dogs and swine than in ponies and goats.

Critical comparison of dosage regimens for aspirin ($\mathrm{pK_a}$ 3.5) is most informative (Table 3.3). Although the dose (10 mg/kg) that will produce analgesia is the same for dogs and cats, the interval between successive doses to maintain analgesia is much longer for cats (Davis 1979). This can be attributed mainly to the slow rate of hepatic biotransformation of salicylate in the cat, since this species has a relative deficiency in microsomal glucuronyl transferase activity. A direct consequence of the difference in rate of salicylate metabolism is that the half-life ($t_{1/2}$) of the drug is four to five times longer in cats than in dogs. To maintain an effective plasma concentration of salicylate in cows, the dose (100 mg/kg) is far higher than in monogastric species and might be attributed to the diluting effect of ruminal fluid. The dosage interval, 12 hours, is based on the rate of salicylate absorption ($t_{1/2,a}$ [absorption half-life] = 2.9 hours) rather than on the elimination half-life ($t_{1/2}$ = 0.54 hour) of the drug.

Bioequivalence. Bioequivalence assessment relies on the concept that pharmaceutically equivalent drug

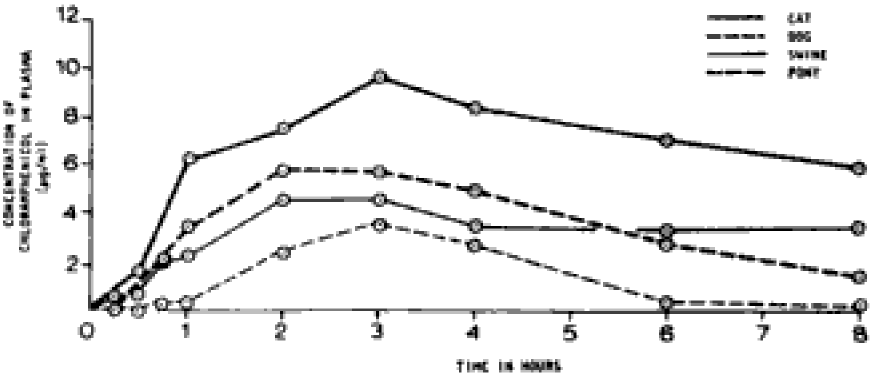

FIG. 3.6—The time course of chloramphenicol concentrations in plasma of domestic animals after oral administration of chloramphenicol (22 mg/kg) in capsules. The drug was undetectable in plasma of goats. Each point represents the mean drug concentration determined in 4 cats or dogs and 8 swine, ponies, and goats (Davis et al. 1972).

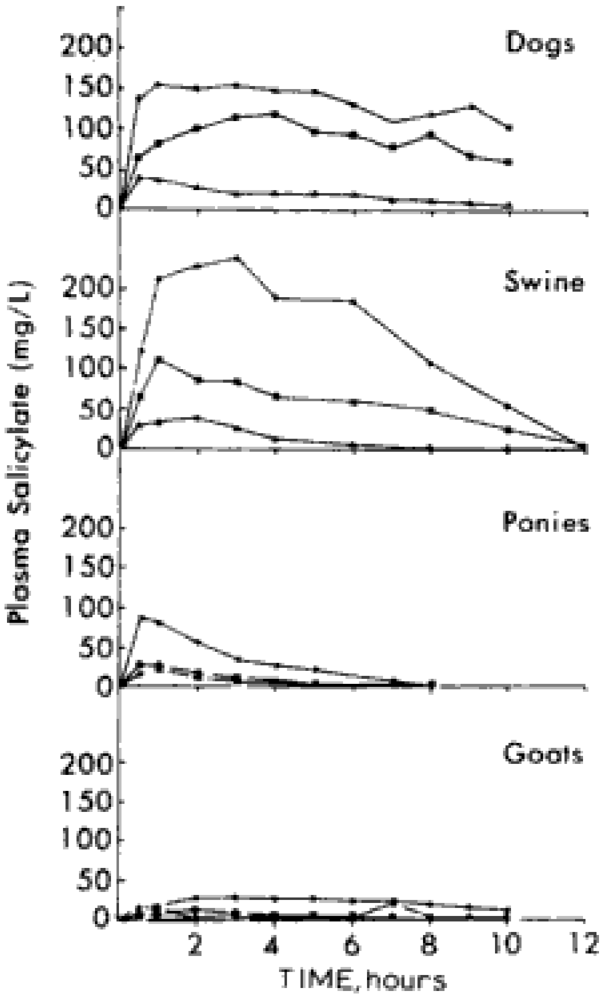

FIG. 3.7—Species differences in absorption of sodium salicylate after oral administration of the drug contained in gelatin capsules. Three dose levels (18.5, 50, and 133 mg/kg) were studied. Data points represent means from at least 4 animals (Davis and Westfall 1972).

products which provide essentially equivalent plasma concentration profiles, in terms of rate and extent of absorption, will produce the same pharmacologic response (therapeutic effect). Two drug products are considered to be bioequivalent when the rates and extents of absorption of the active ingredient in the two products are statistically equivalent to each other according to predetermined criteria under controlled test conditions. The intended analysis should dictate the design of a bioequivalence study, since design constrains the analysis that can be performed. Comparison of the test product (often generic) with a reference product (often pioneer) is based on an estimate of relative bioavailability together with a measure of the uncertainty (variance) of the estimate. Certain parameters obtained from plasma concentration-time curves provide the best estimate of relative bioavailability. These parameters include AUC, observed peak plasma concentration (C_{max}), and time of the observed peak (t_{max}). The AUC, often estimated by the trapezoidal rule, measures extent of absorption. The C_{max} and t_{max} provide an indication of the rate of absorption. When designing bioequivalence studies, blood-sampling times should be selected to characterize C_{max} and t_{max} well, and sample collection should extend for a period that will enable complete description of the plasma concentration profile (from time of drug administration to limit of quantification of the drug). The latter ($AUC_{0\text{-}LOQ}$) should capture 90% of the total AUC extrapolated to infinite time.

Statistical evaluation of bioequivalence studies should be based on confidence interval estimation rather than hypothesis testing (Westlake 1988). The confidence interval approach, using $1 - 2\alpha$ or 90%, is applied to the difference of individual parameters (AUC, C_{max}, and t_{max}). The entire 90% confidence interval should lie within the limits of -0.2 to $+0.2$ multiplied by the mean of that parameter for the reference product. The values of -0.2 and $+0.2$ are historical limits which may be constrained or expanded based on the characteristics of the drug (i.e., the safety margin or

therapeutic window for the compound). Ratios of the parameters can also be used instead of differences, with the corresponding limits being 0.8 to 1.25.

DISTRIBUTION OF DRUGS. Drugs are conveyed throughout the body in the circulating blood and reach tissues of each organ in an amount determined by blood flow and blood concentration to the organ. Concentrations attained in the tissues depend upon the ability of the drug to penetrate capillary endothelium (influenced mainly by binding to plasma proteins) and diffuse across cell membranes.

The pattern of distribution describes the relative amount or concentration of drug that enters each organ and tissue. This can be found only by measuring drug concentrations in each part of the body (including the GI contents) at an appropriate time after its administration. Differences in body composition (Table 3.4), notably in the contribution of the GI tract with its contents and the skeletal muscle to the percentage of body weight, may largely account for species variations in drug distribution. In general, the kinetics of drug distribution in blood, organs, and tissues depend on dose and route of administration, lipid solubility of the drug, extent of binding to plasma proteins and extravascular tissue constituents, and blood flow rates through organs and tissues. Certain drugs such as thiopental undergo redistribution into poorly perfused tissues (e.g., fat and muscle) after initially attaining high concentrations in well-perfused tissues, such as brain, liver, and kidney. The biphasic distribution pattern of this drug can be attributed to differences in blood supply to various tissues.

An outline of the distribution pattern of a drug can be obtained by use of whole-body autoradiography. Uneven distribution of a drug within an organ such as the kidney (Whelton et al. 1971) can affect the success of therapy. Since critical areas for bacterial infection in the kidney are medullary and papillary tissues, knowledge of the intrarenal distribution pattern of antibiotics would greatly assist with selection of an antibacterial agent for treatment of pyelonephritis.

Plasma Protein Binding. Binding of a drug to plasma proteins restricts its distribution, thereby limiting its receptor availability, and can influence elimination of the drug from the body. Protein binding is a reversible interaction, which implies that the drug-protein complex serves as a circulating reservoir of potentially active drug. As an example, the principal active metabolite of ceftiofur, desfuroylceftiofur, is extensively protein bound, which serves to increase the half-life from the typical 1 hour observed with most cephalosporins to approximately 10 hours in cattle (Brown et al. 1991). Microbiological activity after ceftiofur has a similar prolonged half-life (Clarke et al. 1996). Among factors that can affect equilibrium between the free and bound drug are the protein concentration, drug affinity for the binding sites, presence of disease states that alter concentration of certain

TABLE 3.5—Plasma protein binding of drugs in dogs at therapeutic concentrations

*This concentration exceeds therapeutic range for digoxin (cf. Table 3.19).

endogenous compounds (free fatty acids) in the plasma, and presence of other drugs or their metabolites. The plasma protein to which the majority of drugs bind is albumin. Each drug binds to a characteristic extent, usually expressed as a percentage of the total concentration of the drug in plasma (Table 3.5). Binding of different drugs in the same chemical class (sulfonamides, penicillins) can vary widely. The influence that an alteration of molecular structure can have on the percent of drug binding is clearly shown by comparing the binding of digitoxin (89%) and digoxin (27%) in dogs, since these complex molecules differ only in the presence of a hydroxyl group.

The binding capacity of plasma proteins for a drug (moles/g protein) and the dissociation constant of the drug-protein complex (moles/L) quantitatively describe the interaction. Values of these parameters characterizing the binding of some drugs in horse plasma are given in Table 3.6.

The extent of protein binding can be measured by in vitro techniques (equilibrium dialysis, ultrafiltration), which can be compared with the value obtained by measuring equilibrium concentrations of the drug in plasma and transcellular fluid collected simultaneously. Only the lipid-soluble, nonionized moiety of an organic electrolyte that is free (unbound) in the plasma can penetrate cell membranes, diffuse into transcellular fluids (cerebrospinal, synovial, ocular), and enter the milk. At equilibrium the concentration of drug in transcellular fluid will approximate free drug concentration in plasma, which may be only a fraction of total concentration in plasma. This relationship has been shown in vivo for penetration of amphetamine (Baggot et al. 1972) and diazepam (Kanto et al. 1975) into CSF and passage of cloxacillin and ampicillin (Howell et al. 1972) into synovial fluid. The same principle can be applied to the passage of weakly acidic (pK_a >9) and basic (pK_a <5) drugs as well as neutral molecules (chloramphenicol, digoxin) into milk and saliva. For most organic electrolytes the degree of ionization in milk (pH 6.5–6.8) and saliva (pH varies with species) will influence the final concentration attained.

Extensive (>80%) protein binding of a drug restricts its extravascular distribution and may either hinder or facilitate elimination, depending on the mechanism of the process. In terms of renal handling of drugs, protein binding decreases availability of a drug for glomerular filtration (a passive process) but does not interfere with carrier-mediated tubular excretion. Certain disease conditions, such as hypoalbuminemia (nephrotic syndrome) or the uremic state (chronic renal failure), and competition between drugs for albumin-binding sites (drug displacement effect, e.g., warfarin by phenylbutazone) can cause an increase in the percentage of free drug in plasma. Consequently, more is available for distribution to the site of action (as well as other tissues) and an enhanced pharmacologic response can result. Decrease in protein binding is likely to assume clinical importance only for drugs that are extensively bound (Table 3.7). Protein binding can be seen in perspective by considering the fraction in plasma compared with overall distribution of the drug in the body.

Conversely, conditions that increase the amount of protein in the extracellular fluid or that allow increased plasma protein leakage extravascularly (e.g., infection) can enhance total drug concentrations locally in the protein-rich fluid. Clarke et al. (1996) showed this for ceftiofur in infected tissue chambers.

Even though variation among species in protein binding of a number of drugs is statistically significant, classification of drug binding as extensive (>80%), moderate (50–80%), and low (<50%) generally negates interspecies variation; however, this is adequate for clinical purposes. Species variation in binding does not relate to total protein concentration in plasma (apart from avian species versus mammals) due to the excess amount of protein molecules to which drug molecules can bind, but may be attributed at least tentatively to

TABLE 3.6—Parameters describing quantitative aspect of drug-protein binding in horse plasma

Drug	Binding capacity	Dissociation constant	Reference
	(moles/g)	*(molar)*	
Penicillin G	39.0×10^{-6}	2.13×10^{-3}	Dürr 1976
Ampicillin	46.5×10^{-6}	22.70×10^{-3}	Dürr 1976

TABLE 3.7—Drugs that are extensively (>80%) bound to plasma proteins

Drug	Principal pharmacologic effect
Phenylbutazone*	Antiinflammatory
Warfarin*	Anticoagulant
Furosemide*	Diuretic
Digitoxin	Positive inotropic effect, heart rhythm stabilizer
Ceftiofur	Antimicrobial agent
Propranolol	β-adrenergic receptor blockade, antiarrhythmic
Quinidine	Antiarrhythmic, myocardial depressant
Phenytoin*	Anticonvulsant, antiarrhythmic
Diazepam*	Sedative, anticonvulsant
Valproate	Anticonvulsant

*Decreased binding in plasma of uremic patients causes an increase in the percentage of free (unbound) drug.

TABLE 3.8—Range of drug binding to plasma proteins in a variety of mammalian species

Drug	Range of binding (%)
Propranolol	88–99
Digitoxin	83–93
Phenytoin	73–85
Sulfisoxazole	65–86
Amphetamine	20–40
Digoxin	18–36
Morphine	12–34

Note: Total protein concentration in plasma of all mammalian species is within the range 6.0–8.5 g/mL.

differences in composition and conformation of plasma albumin. The range of plasma protein binding of some drugs at therapeutically relevant concentrations is given in Table 3.8 for various species. Species represented include the human, monkey, horse, cow or goat, dog, cat, and rabbit.

Quantitating Drug Distribution. Just as with drug absorption, the distribution of drugs in the animal can be quantified in terms of rate and extent of distribution by evaluation of plasma concentrations over time. However, such evaluation cannot determine the rates and extents of distribution to specific tissues without actually acquiring data over time in those tissues. Rather, the rate and extent of systemic distribution is defined as a weighted average of the rates and extents of distribution to specific tissues within the body.

RATE OF DISTRIBUTION. Plasma concentrations decline very rapidly shortly after administration of an IV dose. The rate of that decline is dependent upon the ability of the drug to distribute from the bloodstream into extracellular fluids and tissues. The rate of distribution can be described as a half-life of distribution, interpreted as the time it takes for 50% of the drug in the plasma to distribute outside of the bloodstream.

EXTENT OF DISTRIBUTION. The extent of distribution is described in terms of volumes of hypothetical fluid compartments, with larger volumes of distribution reflecting more extensive distribution from plasma into tissues. Recall that no relationship exists between distribution volumes for drugs and physiologic spaces. Rather, the value of Vd serves as a proportionality constant relating plasma concentration of a drug to total amount of drug in the body at any time after pseudodistribution equilibrium has been attained:

$$\mathrm{Vd} = \frac{A_{B(t)}}{C} \tag{3.9}$$

where C_p and $A_B(t)$ are plasma concentration and amount of drug in the body respectively at time t. This pharmacokinetic term can be defined as the volume of fluid that would be required to contain the amount of drug in the body if it were uniformly distributed at a concentration equal to that in the plasma. While the volume of distribution provides an estimate of the extent of distribution of a drug, it does not distinguish between widespread distribution and high affinity (selective) binding with restricted distribution. The pattern of distribution must be related to both value of Vd and physicochemical properties of the drug (lipid solubility, ionic character of functional groups) that govern diffusion across biologic membranes and binding to tissues. One cannot tell in which tissue the drug concentrates by looking at the volume of distribution, but one can determine the fraction of drug that is outside the plasma (f_o):

$$f_o = A_{B(t)} - (C \cdot \mathrm{V}_p) \tag{3.10}$$

where V_p is the plasma volume in the animal.

An estimate of the extent of distribution of a drug is given by the pharmacokinetic term, apparent volume of distribution (Vd, mL/kg), which can be calculated according to

$$\mathrm{Vd}_{\mathrm{area}} = \frac{D \cdot F}{\mathrm{AUC} \cdot \beta} \tag{3.11}$$

where AUC represents the total area under the plasma drug concentration versus time curve from $t = 0$ to ∞, F is the bioavailability of the dose administered by that route of administration, D is the administered dose, and β represents the slope of the terminal disappearance portion of the plasma concentration-time profile when plotted as the natural logarithm of concentration (Y-axis) versus time (X-axis).

A more straightforward but less accurate method for calculating volume of distribution entails extrapolating the linear terminal phase of the drug disposition curve to its intercept on the ordinate (plasma drug concentration axis) and substituting this value (B, mg/L) in the expression

$$\mathrm{Vd}_B = \frac{D \cdot F}{B} \tag{3.12}$$

Since the extrapolation method neglects the distribution phase of drug disposition, it is valid only for drugs that behave according to a one-compartment model (distribute almost instantaneously). Otherwise, this method gives an overestimate of the Vd value.

The volume of distribution at steady-state (Vd_{ss}) provides an estimate of drug distribution which is independent of elimination processes, and which is most useful for predicting plasma concentrations upon multiple dosing to a steady-state, or pseudo-equilibrium (Martinez 1998a). The Vd_{ss} is proportional to the amount of drug in the body versus the plasma drug concentration at steady-state. The following equation defines Vd_{ss}:

$$\mathrm{Vd}_{ss} = \frac{D \cdot F \cdot \mathrm{AUMC}}{\mathrm{AUC}^2} \qquad (3.13)$$

All of the various volumes of distribution may be calculated from a plasma concentration-time profile. In general, Vd_{β} overestimates the true volume of distribution, and Vd_{area} is generally an overestimate relative to Vd_{ss}.

Species differences in volume of distribution, notably between monogastric (dogs, cats) and ruminant (cattle, sheep, goats) animals, have been found, particularly with lipid-soluble organic bases. Following parenteral administration, these drugs diffuse into ruminal liquor (in which they may become trapped by ionization) as part of their normal pattern of distribution. The colon of the horse, by acting similarly as a reservoir, can contribute to a value of Vd (in L/kg) intermediate between those found in small animals and ruminant species.

Knowledge of volume of distribution is required for calculating the dose that must be administered to provide a certain (therapeutic) concentration of drug in plasma (C_{ther}):

$$\begin{array}{ccccc} D & = & C_{ther} & \cdot & \mathrm{Vd}_{area}/F \\ (\mathrm{mg/kg}) & & (\mathrm{mg/L}) & & (\mathrm{L/kg}) \end{array} \qquad (3.14)$$

When the drug is administered by other than the IV route, its bioavailability (F) may be less than 1.0 and must be taken into account.

MECHANISMS OF DRUG ELIMINATION. Mechanisms of drug elimination are biotransformation (metabolism) and excretion. Although it is usual for one mechanism to predominate, both hepatic metabolism and renal excretion are involved in elimination of most drugs. The fate of a drug is largely determined by certain of its physicochemical properties, specifically lipid solubility and degree of ionization. Lipid solubility appears to be a prerequisite for biotransformation of drugs by the hepatic microsomal enzyme system. Polar drugs and many drug metabolites are excreted by the kidneys. Widespread extravascular distribution, which is a feature of lipophilic organic bases, and selective tissue binding, such as localization of thiopental in body fat, reduce the rate of elimination of a drug by limiting its accessibility to eliminating organs (drug concentration in the blood flowing to the organs of elimination is very low). Influence of extensive plasma protein binding on elimination of a drug appears to be determined by renal and hepatic mechanisms involved in this process. Apart from the liver, metabolism of drugs takes place in blood plasma and lumen of the gut, where hydrolytic and reductive reactions may occur, as well as in other tissues (intestinal mucosa, kidney, lung). Plasma pseudocholinesterase, which varies in activity according to species, hydrolyzes drugs of widely different pharmacologic classes. An ester linkage is a feature of drugs that undergo hydrolysis. These include acetylcholine, succinylcholine, atropine, procaine, meperidine, aspirin to salicylate, ceftiofur to desfuroylceftiofur, and hetacillin to ampicillin. The selective toxicity of malathion (an organophosphate) for insects rests on the difference in metabolism of the drug between insects and mammals. Insects preferentially convert malathion to malaoxon, which is the effective pesticide, whereas mammals rapidly deesterify the compound to an inactive metabolite. Halogenated volatile anesthetics (halothane, methoxyflurane) are eliminated predominantly unchanged by the lungs (pulmonary excretion) but undergo some degree (5–20%) of metabolism in the liver. Although metabolism is the minor mechanism of their elimination, accumulation of metabolites, which can occur in patients with impaired renal function, can give rise to toxicity.

Drug Metabolism (Biotransformation). Drugs undergo metabolic changes in the body that are directed primarily toward formation of metabolites that have physicochemical properties favorable to their excretion. Products of biotransformation are generally less lipid-soluble and more polar in nature. The latter feature renders metabolites suitable for carrier-mediated excretion processes as well as more likely to be partitioned into the aqueous fluids of the body such as the bloodstream, rendering higher concentrations being presented to the organs of excretion (e.g., kidneys).

Elimination of drug by metabolic alteration can be either limited by the rate of presentation to the organs of biotransformation, or limited by the capacity of the enzymatic system involved in the biotransformation. For drugs that are presentation-limited, alterations in blood flow to the liver (or other organs responsible for metabolism) can dramatically alter the rate of alteration. Changes in the rate of metabolism of coumarin, a flow-rate limited xenobiotic, are predictive of liver blood flow in beagle dogs (Ritschel and Vachharajani 1993).

Drug metabolism has been generally divided into two types of reactions, termed phase I and phase II reactions (Fig. 3.8). The initial phase consists of reactions that can be classified as oxidative, reductive, and

FIG. 3.8—The general pattern of drug metabolism. (Adapted from Williams 1967)

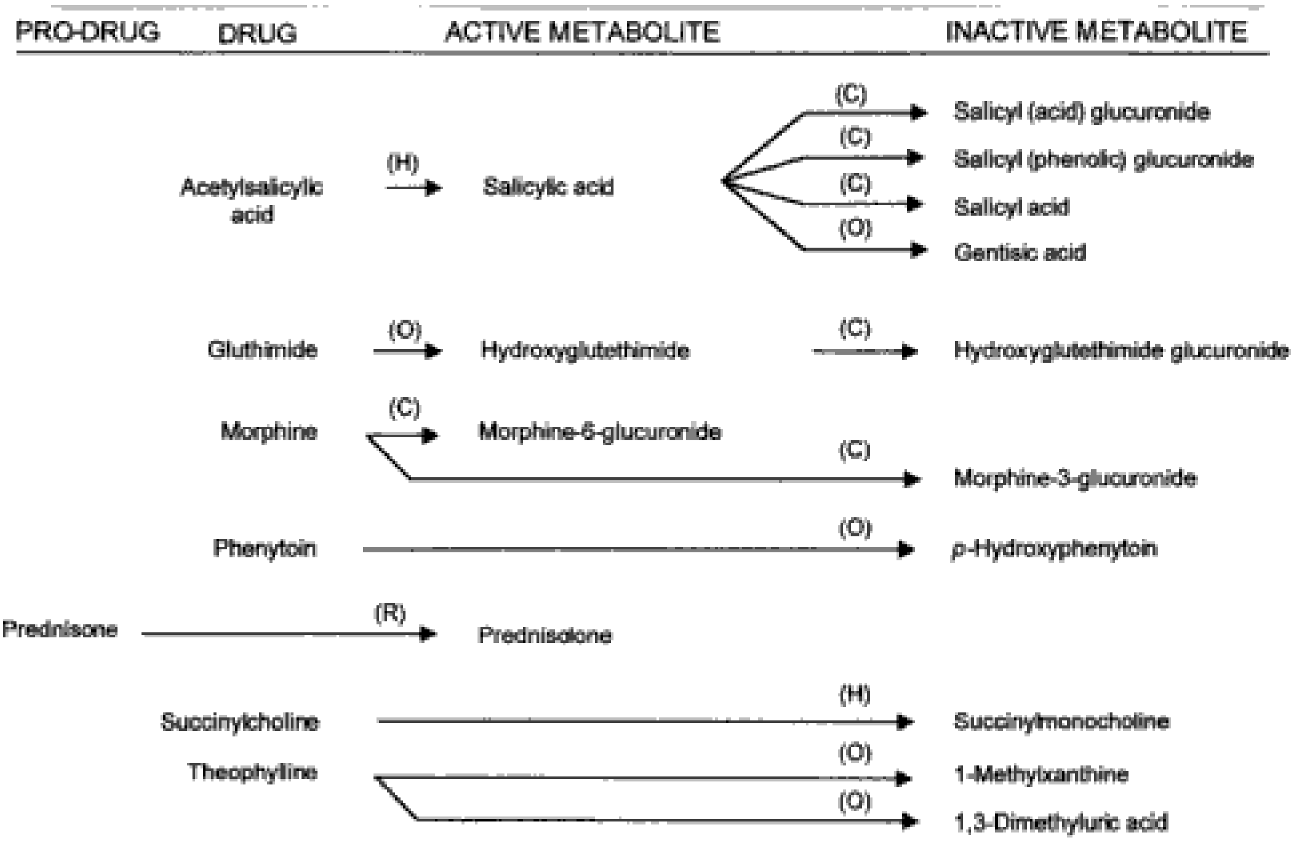

FIG. 3.9—Patterns of biotransformation of representative drugs. Only representative metabolic pathways are shown for some drugs. Inactive concentrations obtained following the therapeutic administration of the parent drug. (O) = oxidation; (R) = reduction; (H) = hydrolysis; (C) = conjugation.

hydrolytic, while the second phase includes the synthetic reactions (conjugations). Phase I transformations usually unmask or introduce into the drug molecule polar groups such as —OH, —SH, —COOH, and —NH_2. These functional groups enable the compound to undergo conjugation with endogenous substances such as glucuronic acid, acetate (acetylation), sulfate (sulfuric acid ester formation), and various amino acids (primarily glutathione, cysteine, and glycine). The drug conjugates formed are water soluble and almost invariably inactive pharmacologically (Fig. 3.9). The most likely metabolic pathway can be qualitatively predicted on the basis of the functional group in a compound (Table 3.9) and the predominant metabolizing reactions found in each species. The results of in vitro studies of drug metabolic pathways for various model compounds show that species differences in metabolic activity are principally quantitative (Table 3.10). It should be noted, however, that it is virtually impossible to quantitatively predict the relative concentrations of metabolites that will be produced after administration of a drug in any given species.

TABLE 3.9—Probable biotransformation pathways for drugs

Functional group	Biotransformation pathways
Aromatic ring	Hydroxylation
Hydroxyl	
Aliphatic	Chain oxidation, glucuronic acid conjugation, sulfate conjugation (to lesser extent)
Aromatic	Ring hydroxylation, glucuronic acid conjugation, sulfate conjugation, methylation
Carboxyl	
Aliphatic	Glucuronic acid conjugation

Primidone	Phenobarbital, phenylethymalonamide
Spironolactone	Canrenone
Conversion of inactive drug (pro-drug) to active drug	
Prontosil	Sulfanilamide
Hetacillin	Ampicillin
Parathion	Paraoxon

decline in plasma concentrations and effects of a drug suggests that one or more of its metabolites may have pharmacologic activity. The only way to determine the activity of a metabolite is to administer the metabolite and study its pharmacokinetic/pharmacodynamic relationship. Many compounds are metabolized to active metabolites, either with therapeutic implications (e.g., ceftiofur to desfuroylceftiofur, procainamide to *N*-acetylprocainamide, ramipril to ramiprilat) or toxicologic implications. Metabolic conversion of parathion (nontoxic per se) to paraoxon (a powerful inhibitor of cholinesterase) and the formation of fluorocitrate (a specific inhibitor of the enzyme aconitase) from fluoroacetic acid and fluoroacetamide are examples of lethal synthesis.

Oxidation is the most prominent reaction in the metabolism of most compounds, including lipid-soluble drugs and steroid hormones. Specifically, many of these enzymes that are located predominantly in parenchymal cells of metabolizing organs (liver, kid-

ney, intestinal epithelium), where they are associated with the smooth-surfaced endoplasmic reticulum. When many tissues including liver are homogenized, endoplasmic reticulum is broken down to form small vesicles known as microsomes. These enzymes, which have a specific requirement for reduced nicotinamide adenine dinucleotide phosphate (NADPH) and molecular oxygen, have been classified as mixed-function oxidases and are termed *microsomal enzymes* because of their association with, and continued activity within, microsomes.

Ability of the microsomal drug-metabolizing enzymes to mediate a wide variety of oxidative reactions may be ascribed to a common mechanism, hydroxylation (Brodie et al. 1958; Gillette 1963, 1966). The mixed-function oxidase mechanism requires that NADPH reduce cytochrome P-450, which is the oxidizing enzyme found in microsomes. Reduced cytochrome P-450 reacts with molecular oxygen to form an active oxygen intermediate. Interaction between this complex and a lipid-soluble drug or steroid substrate yields a hydroxylated substrate, oxidized P-450, and an equivalent molar fraction of water (Fig. 3.10). There are several isoenzymes of cytochrome P-450, each of which has certain substrates it most efficiently metabolizes (Benet et al. 1996). This results in a wide variety of oxidative reactions known to occur in microsomes and include aromatic hydroxylation, aliphatic oxidation, *O*- and *N*-dealkylation, oxidative deamination, replacement of S by O (desulfurization), and sulfoxide formation. In Table 3.12, examples are given of drugs that are metabolized predominantly by hepatic microsomal oxidation. It is common for a drug to be metabolized along two or more pathways simultaneously, in which case, amounts of the metabolites formed depend on the relative activities of different metabolizing enzyme systems. The prevalence of these various isoenzymes is different from organ to organ within an species, by species for a specific organ (Witcamp et al. 1991), and by age within a species and organ type (Kawalec and El Said 1990, 1994). As an example, amphetamine is metabolized along two oxidation pathways (aromatic hydroxylation and oxidative deamination), and the metabolites in turn undergo conjugation reactions (Fig. 3.11). The extent to which these metabolic reactions take place appears to vary with the species (Dring et al. 1970; Baggot and Davis 1973). Acetaminophen, an analgesic and antipyretic agent, has a free hydroxyl group that makes this molecule suitable for conjugation reactions (Fig. 3.12). The glucuronide and sulfate ester formed are highly polar and pharmacologically inactive compounds that are rapidly excreted in urine. Cats are particularly susceptible to acetaminophen toxicity due, in part, to defective conjugation of the drug and conversion to a reactive electrophilic metabolite. Phenacetin and acetanilid, which are precursors of the more polar acetaminophen, are transformed to the latter by the microsomal oxidative reactions of *O*-dealkylation and aromatic hydroxylation respectively (Brodie and Axelrod 1948; Brodie and Axelrod 1949). Biotransformation of phenylbutazone involves aromatic hydroxylation to oxyphenbutazone (an anti-inflammatory agent and drug

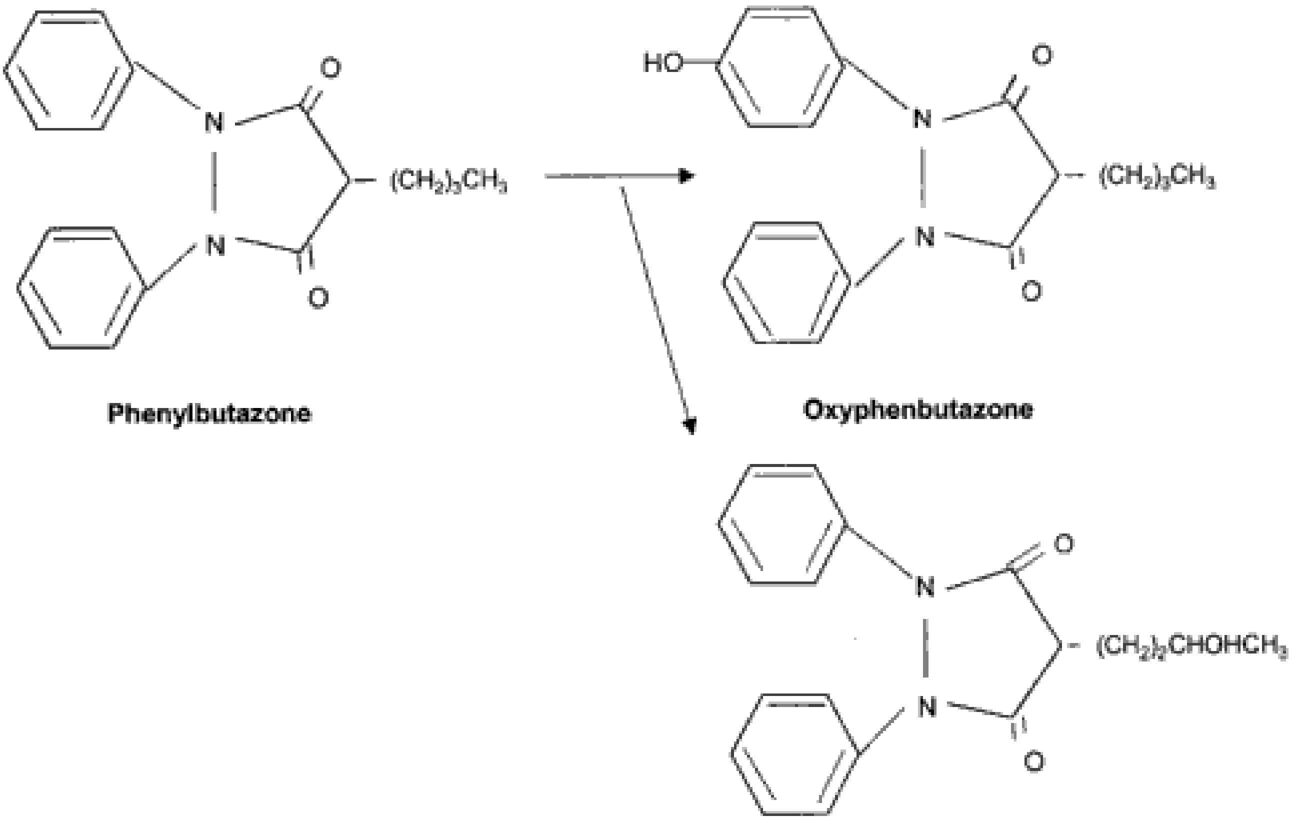

FIG. 3.13—Oxidative metabolic transformations of phenylbutazone.

in its own right) and oxidation of the side chain to a metabolite with only uricosuric action (Fig. 3.13). Oxyphenbutazone in turn forms a glucuronide and sulfate ester. Extensive plasma protein binding of phenylbutazone and its metabolites prior to conjugation limits their availability for glomerular filtration. While long-chain fatty acids undergo microsomal ω oxidation, side-chain alkyl substituents in otherwise lipophilic molecules are characteristically metabolized in the subterminal (ω-1) position, e.g., as in pentobarbital, meprobamate, and ethosuximide. This seems to be a metabolic reaction to avoid formation (by ω oxidation) of a lipophilic carboxylic acid that, like the long-chain fatty acids themselves, would inhibit cytochrome P-450 by detergent action on the lipophilic membrane to which it is attached and on which it is dependent (Stenlake 1979).

Species variations in duration of action of a lipid-soluble drug can often be attributed to differences in the rate of its biotransformation (Dalvi et al. 1987). Reduction of cytochrome P-450 may be rate-limiting in hepatic microsomal oxidative reactions; species differences in P-450 reductase activity have been shown to parallel differences in rates of drug oxidation (Davies et al. 1969). Comparison of half-lives of some drugs that are eliminated to a large degree by hepatic microsomal oxidative reactions shows that the activity of this system is far lower in humans than in domestic and laboratory animal species.

In addition to catalyzing various oxidative reactions, hepatic microsomes can reduce azo and nitro compounds to corresponding amines. Both reductive reactions involve anaerobic conditions, require NADPH, and are almost certainly mediated by enzymes that contain flavine adenine dinucleotide (Mueller and Miller 1950). Azo compounds undergo reductive cleavage to primary aromatic amines. Prontosil, an azo dye, is reduced to sulfanilamide, which has antibacterial activity. The nitroreductase system is partly responsible for inactivation of chloramphenicol. Ruminal microflora and intestinal bacteria can very effectively carry out these reductive reactions. Reductive dehalogenation of volatile anesthetics (halothane, methoxyflurane) is almost certainly mediated by hepatic microsomal enzymes.

Foreign compounds (xenobiotics) can be metabolized by other than the microsomal enzyme system. Nonmicrosomal metabolic reactions include oxidation of alcohols and aldehydes, reduction of ketones, deamination by monoamine oxidase (MAO), and most types of synthetic (i.e., phase II) reactions. Hydrolysis of esters and amides is readily catalyzed by a variety of hydrolytic enzymes present in blood plasma and other tissues, including liver and kidney. Ruminal microorganisms and gut bacteria mediate hydrolytic and reductive reactions (Williams 1972).

Alcohol dehydrogenase and aldehyde dehydrogenase are rather nonspecific enzymes found in the soluble fraction of liver that catalyze important oxidative transformations. Substrates include endogenous compounds (vitamin A, retinine) as well as some drugs (ethanol, propranolol, chloral hydrate). The major metabolic pathway for the hypnotic drug chloral hydrate is reduction to trichloroethanol, which is pharmacologically active. In catalyzing this reaction, alcohol dehydrogenase functions as a reductase (Friedman and Cooper 1960). Chloral hydrate has an apparent half-life of 3 minutes in the dog; the drug is rapidly and quantitatively converted to trichloroethanol (Garrett and Lambert 1973). This metabolite undergoes conjugation with glucuronic acid, and the conjugate is excreted in urine and bile. Likewise, metabolism of ethylene glycol (the primary component in antifreeze) is converted to toxic metabolites including oxalic acid by alcohol dehydrogenase. For this reason, an historic treatment for antifreeze intoxication was administration of ethanol, which competitively inhibits the formation of the toxic metabolite.

MAO, a flavoprotein located in the outer membrane of the mitochondria, is widely distributed in a variety of tissues (liver, kidney, intestinal mucosa, lung, blood vessels and plasma, heart muscle, brain, neurons). Tissue distribution of this enzyme is such that it is readily available to deaminate the biogenic amines. Following release of norepinephrine from adrenergic nerve terminals, it interacts with certain adrenergic receptors on effector cells. Excess is removed from the extracellular region largely by reuptake into the nerve terminal by active transport and to some extent by diffusion away from the site and subsequent enzymatic inactivation by extraneuronal catechol-*O*-methyl-transferase. Within the nerve terminal, norepinephrine is partitioned between a cytoplasmic mobile pool and intragranular pools. That portion present in the former is susceptible to oxidative deamination by MAO. Drugs that inhibit MAO (isocarboxazid, phenelzine, tranylcypromine) can cause an increase in the level of norepinephrine in the brain and other tissues and is accompanied by a variety of pharmacologic effects.

Hydrolysis is an important metabolic pathway for compounds with an ester linkage (—COO—) or an amide bond (—CONH—). Most amides are hydrolyzed more slowly than the corresponding esters. Use of procainamide as an antiarrhythmic is based on its slow rate of hydrolysis compared with that for procaine. Elimination mechanisms for procainamide include hepatic biotransformation (hydrolytic reaction) and renal excretion (Galeazzi et al. 1976). In dogs, over 50% of the dose is excreted unchanged in urine. Formation of the active metabolite *N*-acetylprocainamide is a major metabolic pathway of procainamide in humans and rhesus monkeys (Dreyfuss et al. 1971; Giardina et al. 1976). Since dogs are less able to acetylate primary aromatic amines, they would not form this metabolite as effectively (Papich et al. 1986). Lidocaine undergoes extensive hepatic biotransformation, which varies in pattern among species (Keenaghan and Boyes 1972). The principal metabolic pathways are microsomal oxidation (aromatic hydroxylation, *N*-dealkylation) and hydrolysis of the amide bond, catalyzed by amidases in the soluble fraction of the liver. Phase I metabolites are excreted in urine as such and in the form of conjugates (presumably glucuronides).

PHASE II (SYNTHETIC) REACTIONS. Synthetic (conjugation) reactions may take place when a drug or phase I metabolite contains a chemical group such as hydroxyl (—OH), carboxyl (—COOH), amino (—NH_2), or sulfhydryl (—SH) and is suitable for combining with a natural compound provided by the body to form readily excreted water-soluble polar metabolites (Williams 1971). Conjugating agents include glucuronic acid, glutathione, glycine, cysteine, methionine (for methylation), sulfate (for ethereal sulfate formation), and acetate (for acetylation). These conjugating agents do not, however, react directly with the drug or its phase I metabolite but do so either in an activated form or with an activated form of the drug (as an example, acetyl-coenzyme A rather than acetate). These activated forms are usually nucleotides, and the reaction between the nucleotide and drug or conjugating agent is catalyzed by an enzyme. A conjugation reaction requires a conjugating agent, a nucleotide containing either the conjugating agent or the foreign compound, and a transferring enzyme. Species variations in conjugation reactions can thus depend on occurrence of the conjugating agent, ability of the body to form the necessary nucleotide, or amount of transferring enzyme. In contrast to phase I metabolic reactions, which appear to be ubiquitous throughout mammalian species (at least qualitatively), certain synthetic reactions are either defective or absent in particular species (Table 3.13). The cat synthesizes glucuronide conjugates at a slow rate, as this species is deficient in the transferring enzyme glucuronyl transferase (Dutton 1966). The dog and fox are unable to acetylate aromatic amino groups. Unlike the enhanced potential for drug toxicity imposed on cats by defective glucuronide synthesis, lack of ability to acetylate a particular type of amino group does not appear to hinder elimination of drugs in dogs.

Glucuronide synthesis is a most important phase II metabolic pathway for drugs and certain endogenous compounds (steroid hormones, thyroxine, bilirubin). The activated form of glucuronic acid is the nucleotide uridine diphosphate glucuronic acid (UDPGA), formation of which is catalyzed by enzymes in the soluble fraction of the liver. Synthesis of the glucuronide involves transfer of the conjugating agent from the nucleotide to an acceptor molecule; transfer is mediated by the microsomal enzyme glucuronyl transferase (Isselbacher et al. 1962). This conjugation reaction is unique in that the transferring enzyme is associated with the microsomes, mainly in the liver but also in other tissues.

Some drugs that are excreted largely as glucuronides include morphine, salicylates, acetaminophen, chloramphenicol, iopanoic acid, sulfadimethoxine

TABLE 3.13—Domestic animals with defect in certain conjugation reactions

Species	Conjugation reaction	Major target groups	State of synthetic reaction
Cat	Glucuronide synthesis	–OH, –COOH, –NH$_2$, –SH, $>$NH,	Present but slow rate
Dog	Acetylation	Ar–NH$_2$	Absent
Pig	Sulfate conjugation	Ar–OH, Ar–NH$_2$	Present but low extent

(humans), and the phase I metabolites of diazepam (oxazepam), phenylbutazone (oxyphenbutazone), phenobarbital, and phenytoin. Glucuronide conjugates may be extensively excreted into the bile, the degree of which appears to be determined largely by its molecular weight. This route of excretion may predominate for compounds with molecular weights above 500 and is relatively more common in rats, dogs, and chickens than in other species. Glucuronides that are excreted in bile may undergo hydrolysis (mediated by β glucuronidase) in the intestine. The hydrolytic reaction liberates the drug or the phase I metabolite, which may then be reabsorbed, and an enterohepatic cycle may be established. Not all glucuronides are hydrolyzed by β glucuronidase in the gut (the ester glucuronide of iopanoic acid). Certain breeds of fish do not synthesize glucuronides, which is apparently due to deficiency of the nucleotide UDPGA. Defective synthesis of glucuronides in cats is related to the low level of the transferring enzyme glucuronyl transferase rather than a deficiency of UDPGA. In insects, glucuronide formation is replaced by β-glucoside conjugation (Parke 1968).

Sulfate conjugation is an important alternative metabolic pathway to glucuronidation in metabolism of phenols and, to a much lesser extent, aliphatic alcohols. Some drugs that form ethereal sulfates include phenol, acetaminophen, morphine, isoproterenol, and ascorbic acid. Various endogenous compounds such as chondroitin, heparin, and certain steroids form sulfate esters. Enzymes that catalyze formation of the nucleotide and transfer of the conjugating agent to the acceptor molecule are found in the soluble fraction of the liver (Robbins and Lipmann 1957; Nose and Lipmann 1958). Capacity for sulfate conjugation in the pig is limited and hence can become saturated, yielding a change from a constant fraction of drug metabolized (first order) to a constant amount of drug metabolized (zero order). It appears that the total pool of sulfate in the body can be readily exhausted. For this reason, conjugation with glucuronic acid usually predominates over sulfate formation.

Acetylation of all types of amino groups takes place in humans and several species of animals except the dog and fox, which do not acetylate the aromatic amino group (Williams 1967). The dog appears to have a specific deficiency in arylamine acetyltransferase, although some evidence has been presented that dog liver contains a natural specific inhibitor of this enzyme (Leibman and Anaclerio 1962). Acetylation is the principal metabolic pathway for sulfonamide compounds in humans, rabbits, and rats but is accompanied by aromatic hydroxylation in ruminant species. Sulfanilamide, e.g., undergoes acetylation at both the aromatic and sulfonamido NH$_2$ groups in a variety of species except the canine, which suggests that transacetylases may be specific for the type of amino group (Fig. 3.14). The acetylation reaction takes place in two stages; the first step involves formation of acetyl coenzyme A and is followed by a nucleophilic attack by the amino-containing compound on the acetylated enzyme. This reaction takes place in the reticuloendothelial rather than parenchymal cells of liver, spleen, lungs, and intestinal mucosa (Govier 1965).

Acetylation decreases water solubility as well as lipid solubility (which is usual for conjugates) of sulfonamide compounds. Sulfapyrimidine and probably sulfadoxine and sulfadimethoxine are exceptions in that their acetyl derivatives are more water-soluble. Increased aqueous solubility decreases the potential for crystalluria. Urinary alkalinization increases the solubility of sulfonamides in urine and the fraction of dose excreted unchanged by the kidney.

Sulfhydryl-containing drugs and/or phase I metabolites are subject to conjugation with other molecules containing free —SH groups. These may be either endogenous compounds or xenobiotics. Many of these compounds, including glutathione (G—SH)and cysteine (C—SH), are critical in the maintenance of the proper redox potential within the body and may exist as either the reduced monomer (G—SH or C—SH) or the oxidized dimer (G—SS–G or C—SS–C, namely cystine). Likewise, conjugation of xenobiotics containing free —SH groups with these endogenous redox modulating compounds are subject to interconversion between the reduced form (e.g., desfuroylceftiofur) and the oxidized conjugate (e.g., desfuroylceftiofur glutathione, desfuroylceftiofur cysteine) (Olson et al. 1998). This is one of the few covalently bound conjugations that is readily reversible, depending upon the redox potential of the local environment.

METABOLIC TRANSFORMATIONS MEDIATED BY GI MICROORGANISMS. GI microflora are capable of mediating a wide variety of metabolic transformations, the most prominent of which are hydrolytic and reductive reactions (Scheline 1968, 1973). Microbial metabolism may occur after oral administration of a drug product or following passive diffusion of the nonionized form of a drug from the systemic circulation

into the lumen of the GI tract. Enteric sulfonamides (phthalylsulfathiazole, succinylsulfathiazole) depend on release of sulfathiazole for their antibacterial action. Hydrolysis, mediated by bacterial enzymes in the large intestine, is also responsible for activation of the anthraquinone glycosides (cascara sagrada, senna). Hydrolysis of glucuronide conjugates that are excreted in bile underlies the phenomenon of enterohepatic circulation, since only the drug itself is lipid-soluble and can be reabsorbed. The enzyme responsible for this hydrolytic reaction, β glucuronidase, is found principally in bacteria (*Escherichia coli*) of the large intestine. Microbial glucuronide hydrolysis is necessary for release of bile acids from their conjugates in the intestine, enabling them to play their essential role in fat absorption. Both azo- and nitro-reductase activity are also associated with gut bacteria.

Ruminal microflora catalyze hydrolytic and reductive reactions; e.g., cardiac glycosides are hydrolyzed in the rumen, and chloramphenicol is inactivated by reduction of the nitro (—NO_2) group. Parathion, which is the precursor of the active pesticide paraoxon, may undergo nitroreduction in the rumen. This metabolic reaction reduces both the activity and toxicity of the irreversible anticholinesterase agent.

While GI microorganisms can mediate certain metabolic transformations of drugs, chronic administration of antimicrobial agents can adversely affect activity of these bacteria. Since they are located mainly in the large intestine and rumen, microflora may be exposed to action of an antimicrobial agent irrespective of the route of administration. The extent of bacterial exposure to a drug depends on the extent of absorption from the small intestine and, following parenteral administration, the amount of drug that is excreted into the large intestine and rumen. These translocation processes are determined by the lipid solubility and degree of ionization of the drug.

DRUG BIOTRANSFORMATION IN THE DEVELOPING ANIMAL. Hepatic drug metabolism generally increases from birth, to reach a maximum when the animal is a young adult. As animals age thereafter, metabolism gradually diminishes, with the rate of decrease in biotransformation efficiency increasing as the animal approaches geriatric age. These generalities are fraught with exceptions, and specific situations must be addressed.

In dogs, most mixed function oxidases mature by the fifth to eighth week after birth, with slight decreases after weaning (Kawalek and El Said 1990). Sulfation reactions mature early in dogs, but glucuronidation matures more slowly. This impacts on the metabolism and disposition of acetaminophen, phenobarbital, and phenytoin in dogs (Ecobichon et al. 1988).

In ruminants, clear changes in metabolism result when preruminant animals become ruminants. Cytochrome P-450 and NADPH-dependent reductases increase by 50%; analine hydroxylase increases by threefold; and ethoxycoumarin *O*-deethylase, UDP glucuronic acid glucuronyl transferase, and glutathione *S*-transferase all are increased subsequent to the development of a functional rumen (Kawalek and El Said 1994). Such maturational changes, likely because of the increased complexity of the nutrients being exposed to the liver as a result of the dietary change, is consistent with the quantum increase in the rate of elimination of ceftiofur and desfuroylceftiofur-related metabolites in ruminant cattle compared with preruminant cattle (Brown et al. 1996).

DRUG-INDUCED CHANGES IN RATE OF METABOLISM. Metabolism of a drug generally facilitates its removal from the body. Therefore, an alteration of the rate of metabolism will affect duration of drug action. Among factors that can alter rate of metabolism are certain lipophilic drugs and environmental chemical substances (pesticides, carcinogens) and a reduction in the hepatic blood flow. Decreased binding of extensively bound drugs can increase their availability for metabolism. A number of drugs are capable of stimulating (inducing) the hepatic microsomal enzyme system (phenobarbital, diazepam, phenytoin, phenylbutazone). Enhanced metabolizing capacity represents an increase in concentration of enzyme protein (increased synthesis) rather than increased activity and is referred to as enzyme induction (Conney and Burns 1972). Any drug that is lipid-soluble at physiologic pH is potentially capable of inducing microsomal enzymes when administered on a chronic basis. This phenomenon also has physiologic implications, since the steroid hormones, thyroxine, and bilirubin are substrates for microsomal enzymes.

Drug interactions are manifested as the sequelae attending concurrent use of two or more drugs. A drug such as phenylbutazone, which is extensively bound to plasma albumin and capable of inducing microsomal enzymes, can considerably increase the metabolism of other (particularly acidic) drugs. The influence of induction on pharmacologic action of a drug depends on relative activity of the parent drug and its oxidized product (phase I metabolite).

The rate of drug metabolism can be decreased by inhibition of the process. In addition to microsomal enzymes, others such as plasma pseudocholinesterase and monoamine oxidase are subject to inhibition. Delayed elimination is a direct consequence of inhibited metabolism, and the effect of this on pharmacologic action depends largely on the fraction of the dose normally eliminated by the inhibited metabolic reaction. When a major metabolic pathway is inhibited, the metabolite of a minor pathway may assume greater importance, particularly if this product has toxic potential.

Drugs that inhibit microsomal enzyme activity include cimetidine, chloramphenicol, quinidine, organophosphorus insecticides, and ketaconazole. Chloramphenicol increases duration of pentobarbital anesthesia in dogs and decreases body clearance of both phenobarbital and phenytoin, commonly used anticonvulsant drugs. The ability of some drugs to stimulate or depress the microsomal drug-metabolizing system requires that this possibility be kept in mind when considering multiple drug therapy. Alterations in the half-life of drugs in patients with thyroid dysfunction appear to result mainly from accelerated hepatic microsomal metabolism in hyperthyroidism and retarded biotransformation in hypothyroid patients (Vesell et al. 1975).

Irreversible inhibition of plasma pseudocholinesterase by organophosphorus compounds may in itself cause toxicity or, when inhibition is partial, can provide the circumstance for a drug that is metabolized by this enzyme (succinylcholine) to produce an adverse effect.

Excretion of Drugs. Most drugs are eliminated by a combination of biotransformation and excretion processes. Biotransformation generally enhances the water solubility of drugs, so their metabolites are readily excreted. Polar drugs and compounds with low lipid solubility are eliminated mainly by excretion. Although the kidney is by far the most important organ of excretion, certain compounds are excreted mainly in bile. The liver; salivary, sweat, and mammary glands; and lungs constitute nonrenal routes of excretion. Pulmonary excretion involves diffusion of volatile substances from systemic circulation into pulmonary alveolar spaces, from which they are removed by exhalation.

Drug excretion is a first-order process except in the situation when plasma concentration of a substance exceeds the capacity of a carrier-mediated transport mechanism, in which case excretion obeys zero-order kinetics. When the drug concentration declines to the level at which the system is no longer saturated, the excretion process becomes first order.

RENAL EXCRETION. Renal excretion is the principal process of elimination for drugs that are predominantly ionized at physiologic pH and for compounds with limited lipid solubility. Drugs excreted unchanged (not altered by a metabolic reaction) mainly in urine include many antibiotics (most penicillins, cephalosporins, aminoglycosides, and oxytetracycline), most diuretics (with the notable exception of ethacrynic acid), the competitive neuromuscular blocking agents (*d*-tubocurarine, gallamine), and possibly the cardiac glycoside digoxin.

Renal handling of drugs and drug metabolites is complex and, depending on the physicochemical properties of the substance, the following mechanisms may be involved: glomerular filtration of molecules that are free (unbound) in the plasma; carrier-mediated excretion of certain polar organic compounds by the proximal tubular cells; and pH-dependent passive reabsorption, by nonionic diffusion, of lipid-soluble substances (weak organic electrolytes) in the distal portion of the nephron. In general, compounds that have low lipid solubility and those that are predominantly ionized in blood plasma are rapidly excreted by the kidney, whereas weak organic electrolytes, which are partly nonionized and lipid-soluble, are excreted more slowly.

Extensive (>80%) protein binding hinders a drug's passage through the porous glomerular capillary membrane. The amount of drug that enters the glomerular filtrate is determined by its concentration in plasma water and the rate of glomerular filtration (GFR). Any pharmacologically active substance that lowers arterial blood pressure or constricts renal arterioles will reduce the GFR. The extent of this effect on renal excretion of the drug, however, might be lower than expected if the substance is transported into tubular fluid by a carrier-mediated process.

Carrier-mediated transport of certain drugs and drug metabolites into tubular fluid takes place in the proximal tubule. This process requires an energy source and intracellular carrier substances. The carriers are relatively nonspecific in that they transport either organic acids or organic bases, but their capacity is limited. Above a certain concentration of drug in plasma, the carrier-mediated system becomes saturated and transport proceeds at a constant rate (obeys zero-order kinetics). Some substances excreted by this process are listed in Table 3.14. Extensive protein binding does not hinder tubular excretion of drugs, presumably because the drug-albumin complex dissociates upon removal of free drug from the plasma. Cloxacillin and ampicillin, which are excreted by the same renal mechanisms, have the same half-life (1.2 hours in cows), even though cloxacillin is 80% bound to plasma albumin and ampicillin is only 20% bound.

Concurrent administration of two drugs (either acids or bases) that are substrates for the same carrier-mediated excretion process will cause delayed excretion of the less readily transported substance, e.g., probenecid decreases the rate of elimination of penicillin G and ceftiofur by reducing tubular excretion of the antibiotic (Kampmann et al. 1972; Whittem et al. 1995). Substrate inhibition provides conclusive evidence that a transport process is carrier-mediated.

TABLE 3.14—Drugs excreted by carrier-mediated process in the proximal renal tubule

Acids	Bases
Penicillin G	Procainamide
Ampicillin	Dopamine
Ceftiofur	Neostigmine
Sulfisoxazole	*N*-methylnicotinamide
Phenylbutazone	Trimethoprim
Furosemide	
Probenecid	
p-aminohippurate	
Glucuronic acid conjugates	
Ethereal sulfates	

While a drug may enter tubular fluid by glomerular filtration and proximal tubular excretion, its renal clearance may nonetheless be low. This situation can be explained by substantial reabsorption taking place in the distal nephron. Renal handling of salicylate (an organic acid, pK_a 3.0) in dogs and cats exemplifies this point. Since tubular reabsorption takes place by passive diffusion, only the lipid-soluble nonionized form of a weak organic electrolyte can be reabsorbed. The extent of reabsorption depends on concentration of the drug and its degree of ionization in distal tubular fluid; e.g., weak organic acids are more highly ionized, and thus less well absorbed, in an alkaline than an acidic environment. This concept forms the basis of urinary alkalinization and, perhaps even more effective, the induction of alkaline diuresis to promote excretion of organic acids in cases of overdosage. An underlying requirement for this therapeutic procedure to be effective is that a substantial fraction of the amount of drug in the body be excreted unchanged in urine; i.e., renal excretion constitutes a significant mechanism of elimination for the drug. In humans and probably in dogs, urinary alkalinization increases the excretion rate of salicylate (pK_a 3.0), sulfisoxazole (pK_a 5.0), and phenobarbital (pK_a 7.4), whereas acidification of urine hastens removal of amphetamine (organic base, pK_a 9.9).

The usual urinary pH of carnivorous animals such as dogs and cats is acidic (5.5–7.0), while that of herbivorous species (horses, cattle, sheep) is alkaline (7.0–9.0). In any species, however, urinary pH is dependent mainly on dietary habit. In humans, the urinary reaction is generally acidic but can vary over a wide range of pH (5.0–8.5). Suckling and milk-fed herbivores generally excrete an acid urine; however, following maturity they characteristically excrete an alkaline urine.

BILIARY EXCRETION. Although the kidney is the principal organ of excretion for drugs that are eliminated unchanged and for most drug metabolites, some compounds are excreted mainly by the liver into bile. Properties of a compound that appear to facilitate its biliary excretion include a molecular weight greater than 300–500 and presence of polar groups. Conjugation with glucuronic acid, which takes place in the hepatocytes, may be the determining factor for excretion of a drug or phase I metabolites and certain endogenous substances in bile. Biliary excretion is an important elimination mechanism for organic anions and cations that are too polar to be reabsorbed from the intestine.

Some drugs (nafcillin, erythromycin, digitoxin), iopanoic acid (contrast agent used in cholecystography), certain endogenous substances (steroid hormones), and glucuronide conjugates of a variety of compounds (chloramphenicol, morphine, bilirubin) are excreted to a substantial extent in bile. The relative importance of the biliary excretion route depends mainly on the particular substance and to some extent on species, which may be grouped together as good (rats, dogs, chickens), moderate (cats, sheep), and poor (guinea pigs, rabbits, rhesus monkeys, probably humans) biliary excretors (Williams 1971). This grouping of species is based on the minimum molecular weight for extensive biliary excretion of polar compounds. Species variation in the extent of biliary excretion of drugs is likely to occur with compounds of molecular weight between 300 and 500. When molecular weight of a polar compound exceeds 500, which may be a glucuronide, it will be excreted predominantly in bile of all species. The rate of bile flow has been shown to affect excretion of a number of substances, including bromsulfophthalein and bilirubin (Roberts et al. 1967).

Compounds excreted in bile enter the small intestine. Depending on their lipid solubility, some drugs (e.g., tetracyclines) are reabsorbed. Glucuronide conjugates may be hydrolyzed by β glucuronidase, which is present in the intestinal microorganisms, and the liberated compound may then be reabsorbed. This cycle, consisting of biliary excretion followed by reabsorption from the intestine, is known as the enterohepatic circulation of a drug (Fig. 3.15). When a significant fraction of the dose undergoes enterohepatic circulation, this process delays elimination of the drug. It is usual for the drug and its metabolites to be gradually removed from the body by renal excretion. Enterohepatic circulation increases the half-life of drugs that are eliminated by renal excretion.

Quantitating Drug Elimination. The rate of elimination of a drug is determined mainly by the mechanism(s) of the process. It may be influenced by extensive (>80%) binding to plasma proteins, degree of perfusion of the eliminating organ(s), activity of drug-metabolizing enzymes, and efficiency of renal excretion. Plasma drug concentrations typically decline according to a first-order rate process, meaning that a constant *fraction* of drug is eliminated for each unit of time. In contrast, elimination by a zero-order rate process would indicate that a constant *amount* of drug is eliminated for each unit of time. Graphically, using the same data elimination by a first-order rate process appears curvilinear when plotted as concentration versus time (Fig. 3.16), but appears as a straight line when plotted as the logarithm of concentration versus time (Fig. 3.17).

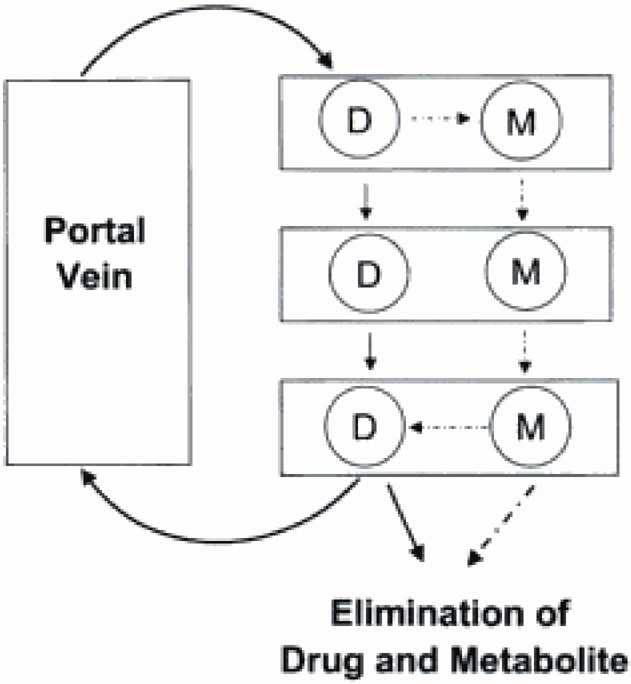

FIG. 3.15—When a drug (D) is absorbed from the intestine, excreted in bile, and reabsorbed from the intestine, it has undergone enterohepatic cycling (solid arrows), a component of distribution. Similarly, when a drug is converted to a metabolite (M) that is secreted in bile, converted back to drug in the intestine, and drug is reabsorbed (dashed arrows), the drug has also undergone enterohepatic cycling, in this case indirectly through a metabolite.

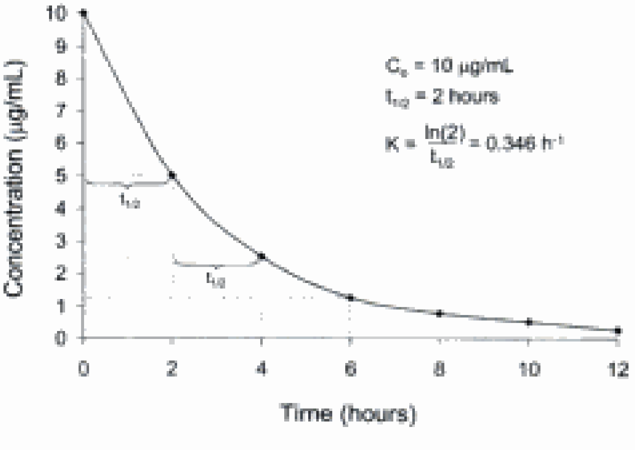

FIG. 3.16—Normal Cartesian graph showing first-order (exponential) decline in plasma concentration of a drug with time. The solid line represents the elimination (linear terminal) phase of the disposition curve.

HALF-LIFE. The elimination half-life of a drug, defined as the time required for the body to eliminate one-half of the remaining drug, is given by the expression:

$$t_{1/2} = 0.693/\beta \qquad (3.15)$$

where β (sometimes defined as K), the overall elimination rate constant, is the negative value of the slope of

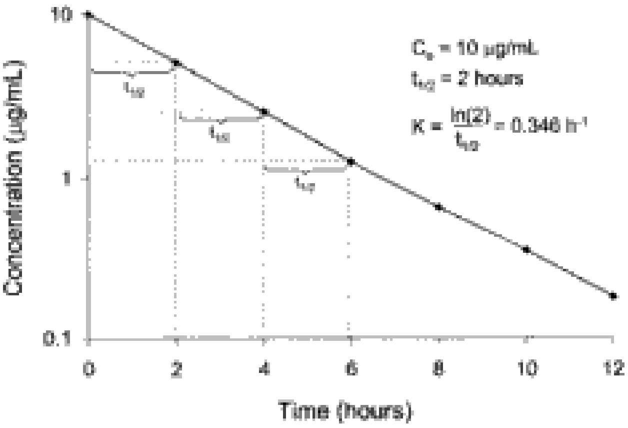

FIG. 3.17—Semilogarithmic graph showing first-order (exponential) decline in plasma concentration of a drug with time. The solid line represents the elimination (linear terminal) phase of the disposition curve.

the elimination (linear terminal) phase of the plot of the logarithm of concentration versus time. A large value of β (or K), corresponding to a short half-life, indicates rapid elimination. The half-life is found simply by measuring the time required for any given plasma concentration of the drug to decline by 50% during the linear phase of the drug concentration-time profile (this can be determined graphically; see Figs. 3.16 and 3.17).

Half-life values of the majority of therapeutic agents are independent of the dose administered, since their overall elimination obeys first-order kinetics. When drug absorption from the GI tract or an injection site is rapid, the half-life is independent of the route of administration. IV injection of a single dose is, however, the only foolproof procedure on which to base the calculation of the true elimination half-life. To ascertain whether a drug has linear pharmacokinetic characteristics, the disposition kinetics should be studied at two or more dose levels.

When drug elimination obeys zero-order (constant-rate) kinetics, the "half-life" becomes progressively longer as the dose is increased, and the drug is said to have nonlinear (or dose-dependent) pharmacokinetics, implying that concentrations at any time after administration are not proportional to the dose administered. The usual cause of dose-dependent elimination is the limited capacity of certain drug-metabolizing enzyme systems (e.g., microsomal glucuronyl transferase activity in cats). Mathematical treatment of nonlinear kinetics is invariably complex (Wagner 1973). The half-life of salicylate is dose-dependent in cats (Yeary and Swanson 1973), phenylbutazone elimination follows zero-order kinetics in dogs (Dayton et al. 1967) and horses (Piperno et al. 1968), and phenytoin half-life is dose-dependent in humans (Houghton and Richens 1974).

The rate of elimination of a drug is usually an important determinant of duration of pharmacologic effect. In this context, half-life is used, along with the range of therapeutic plasma concentrations, to estimate the dosage interval for a drug that is given repeatedly to maintain a particular effect, e.g., digoxin (in treatment of congestive heart failure), phenytoin (as an anticonvulsant), aspirin or acetaminophen (for relief of mild to moderate pain), and theophylline oral dosage forms (bronchodilating effect). When absorption is rapid and complete, the amount of drug remaining in the body at fixed times after administration of a single dose can be estimated from knowledge of the half-life (Table 3.15).

TABLE 3.15—Application of half-life to estimate fraction of the dose remaining in the body, assuming first-order elimination

1	1/2
2	1/4
3	1/8
4	1/16
5	1/32
6	1/64

FACTORS INFLUENCING HALF-LIFE. Any physiologic state or disease condition that alters either access of a drug to the organs of elimination or activity of the eliminating mechanism is likely to cause change in the usual half-life of the drug. For drugs that behave pharmacokinetically according to a two- or three-compartment model (described later), the half-life is a function not only of elimination but also of distribution.

In neonatal animals the biotransformation pathways associated with the microsomal drug-metabolizing enzyme system (oxidation and reduction reactions and glucuronic acid conjugation) are deficient. Their development appears to be biphasic, consisting of a rapid and nearly linear increase in activity during the first 3–4 weeks, followed by slower development up to the 10th week postpartum (Short and Davis 1970). Renal function (both rate of glomerular filtration and, even more so, carrier-mediated proximal tubular excretion processes) is inefficient in neonatal animals of most species, excluding the bovine (Dalton 1968a,b,c). It follows that the half-life of drugs eliminated by microsomal metabolic reactions or by renal excretion will be prolonged in neonatal animals.

Various types of interaction between drugs that are administered concomitantly can affect the half-life. Interference with carrier-mediated transport mechanisms (probenecid decreases proximal tubular excretion of penicillins), displacement from binding sites on plasma proteins (phenylbutazone displaces warfarin from plasma albumin), and stimulation of the hepatic microsomal drug-metabolizing enzyme system (by chronic administration of phenobarbital) or its depression (by chloramphenicol) are interactions that may have clinical significance. Drugs that alter activity of hepatic microsomal enzymes affect the metabolism of endogenous steroids.

TABLE 3.16—Half-life (hours) of some drugs in domestic animals

Drug	Cattle	Horse	Pig	Dog	Cat
Hepatic metabolism					
Salicylate	0.8	1.0	5.9	8.6	37.6[a]
Pentobarbital	0.8	1.5	—	4.5	4.9

Oxytetracycline	9.1	10.5	—	6.0	—

[a] Dose dependent.
[b] Eliminated by hepatic metabolism and renal excretion (30-35%); half-life influenced by urinary pH.
[c] Eliminated by hepatic metabolism and renal excretion (20%).
[d] Influenced by urinary pH reaction.

Urinary pH can influence the half-life of a drug for which tubular reabsorption, a passive nonionic diffusion process, is a feature of its handling by the kidney. The extent of this effect depends on the concentration and degree of ionization of the drug in tubular fluid. An alteration of urinary pH from acidic to alkaline reaction can reduce considerably the reabsorption of weak organic acids with pK_a values within the range 3.0–7.2 and thereby decrease their half-life. The converse will apply to the excretion rate of weak organic bases.

Increase in the half-life of drugs, which are eliminated in healthy animals mainly by renal excretion, is a direct and important consequence of impaired renal function. The relationship between the half-life and body clearance of a drug is given by

$$t_{1/2} = 0.693 \cdot Vd_{area}/Cl_B \qquad (3.16)$$

where Vd_{area} is apparent volume of distribution of the drug and Cl_B is body clearance. When renal clearance represents a substantial fraction of body clearance of a drug, the half-life can be estimated from Eq. 3.11. In patients with reduced renal function, increase in dosage interval, based on the longer half-life, will offset excessive accumulation and toxic effects that might otherwise ensue. Likewise, in patients that have an altered volume of distribution, the half-life will be affected because the concentration of drug being presented to the organs of elimination will be altered. For example, the volume of distribution of gentamicin in neonatal animals is larger due to a larger extracellular fluid volume in neonatal animals compared with adults (Clarke et al. 1985). The resultant apparent elimination half-life of gentamicin is longer in neonates than in adults.

Superimposed on numerous factors influencing the half-life of a drug in an individual animal are intra- and interspecies variations. Considerable variation exists among the species of domestic animals in the half-lives of several drugs (Table 3.16). Although it is not feasible to rank species according to the rate at which they eliminate drugs (expressed as half-life), herbivorous species (in particular, ruminant animals) appear to eliminate drugs that undergo extensive hepatic metabolism (biotransformation) more rapidly than carnivorous species. Most impressive is the rapid elimination of salicylate in ruminant animals and horses compared with the long and dose-dependent half-life of this drug in cats (Davis and Westfall 1972). Clinical application of this wide variation in salicylate elimination is manifest in the dosage interval for sodium salicylate in horses (35 mg/kg, IV at 6-hour intervals) and aspirin in dogs (10 mg/kg, orally at 12-hour intervals) and cats (10 mg/kg, orally at 48-hour intervals) (Davis 1979).

Trimethoprim is generally used in conjunction with a sulfonamide, the choice of which does not appear to be critical in terms of antibacterial action but is supposedly related to their relative rates of elimination in different species. For use in humans trimethoprim is combined with sulfamethoxazole. Since both drugs have approximately the same half-life (10.6 hours), any appropriate dosage interval will take advantage of their synergistic action. Veterinary preparations contain trimethoprim combined with sulfadoxine or sulfadiazine for use in large or small animals respectively. These preparations have been found very effective, even though half-lives of the trimethoprim and sulfonamide do not coincide. Presumably, the dose rates recommended aim at maintaining therapeutic concentrations of sulfonamide with intermittent synergistic action of the combination. Trimethoprim undergoes extensive hepatic biotransformation in domestic animals compared with humans (Table 3.17).

The half-lives of drugs eliminated by renal excretion, in particular by filtration alone, may be shorter in dogs than herbivorous species. This observation is consistent with the higher rate of glomerular filtration in dogs. Apart from these general trends, the only

E(b) = biliary excretion.
*Half-life influenced by urinary pH reaction.

conclusion that can be drawn is that half-life should not be extrapolated from one species to another.

BODY CLEARANCE. Body clearance, which represents total clearance, is considered to be a better index of efficiency of drug elimination than the commonly used half-life. It is based on the concept of the body as a whole acting as a drug-eliminating system and represents the sum of clearances of the drug by eliminating organs (liver, kidneys). Accordingly, body clearance may be defined as the volume of plasma cleared of the drug by various elimination processes per unit time and is expressed in terms of (mL/min)/kg. The value of this parameter can be calculated by dividing the systemically available dose of drug by the total area under the plasma concentration-time curve:

$$\mathrm{Cl}_B = F \cdot \mathrm{dose/AUC} \qquad (3.17)$$

which is equivalent to the expression

$$\mathrm{Cl}_B = 0.693 \cdot \mathrm{Vd}_{area}/t_{1/2} \qquad (3.18)$$

when the drug is completely available systemically (i.e., $F = 1.0$ when the drug is administered IV).

Body clearance differs from half-life in that it allows expression of the rate of elimination of a drug in a manner that is independent of disposition kinetics of the drug (i.e., distribution). The terms body clearance and half-life, which is a hybrid parameter, can be distinguished by comparing the pharmacokinetics of ampicillin and digoxin in dogs. These two drugs have the same body clearance (3.9 mL/min)/kg); the half-life of ampicillin is 48 minutes compared with 1680 minutes for digoxin and is influenced by the apparent volumes of distribution, which are 0.27 L/kg and 9.46 L/kg, respectively. It can be concluded that for drugs with a given clearance value, the smaller the apparent volume of distribution, the shorter the half-life. Values of the major pharmacokinetic parameters describing the disposition kinetics of some antimicrobial agents in dogs are given in Table 3.18.

Since body clearance is the sum of the individual clearance processes, it can be viewed simply as

$$\mathrm{Cl}_B = \mathrm{Cl}_r + \mathrm{Cl}_{nr} \qquad (3.19)$$

where Cl_r is renal clearance and Cl_{nr} is nonrenal clearance of the drug. In the case of a drug that undergoes extensive hepatic biotransformation, the nonrenal clearance represents hepatic (metabolic) clearance and may well approximate body clearance. For a drug that is excreted unchanged in the urine, its renal clearance is principally the sole or at least predominant component of body clearance. Contribution of an eliminating organ to body clearance of a drug can be determined if the fraction of IV dose cleared by the particular organ is known. For the kidney,

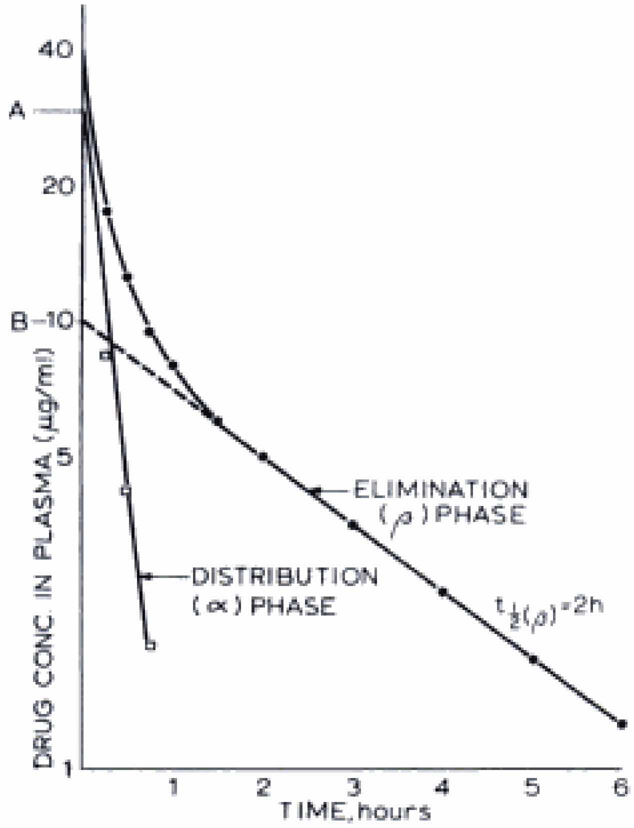

FIG. 3.18—Semilogarithmic graph depicting time course of drug in plasma after IV administration of a single dose. Data points represent experimental (•) and residual (□) plasma drug concentrations. Zero-time intercepts of the distribution and elimination phases of the biphasic disposition curve are *A* and *B*, respectively.

$$\mathrm{Cl}_r = f_{ex} \cdot \mathrm{Cl}_B \qquad (3.20)$$

where Cl_r is renal clearance of the drug and f_{ex} is the fraction of dose excreted unchanged in the urine. Based on this concept, the Cl_B of insulin and *p*-aminohippurate, which are handled by known renal mechanisms and excreted unchanged (i.e., have f_{ex} approximating 1.0), are used to measure the glomerular filtration rate and effective renal plasma flow, respectively.

PHARMACOKINETIC ANALYSIS. Mathematical expression of the relationship between plasma concentrations and time following administration of a drug allows not only for the description of the former, but also estimation of drug plasma profiles following different dosage regimens, disease conditions, and physiologic states. From these estimations, the efficacy and/or toxicity of a drug under these conditions may be more effectively predicted. What follows is only an introduction into this field. Other textbooks provide substantially more detail (Gibaldi and Perrier 1982; Rowland and Tozer 1995).

Compartmental Analysis. Compartmental analysis, in which the body is conceived as consisting of distribution compartments interconnected by first-order rate constants defining drug transfer (i.e., constant fraction of drug transfered per unit of time), is used to describe the pharmacokinetic behavior of drugs. Usually these compartments, which are mathematical entities, have no physiologic counterpart.

Following an IV injection of a single dose of drug, the decline in plasma concentration of the drug is expressed graphically by the disposition curve. For most drugs this curve, plotted in a semilogarithmic manner (i.e., as the logarithm of concentrations over time), is biphasic (Fig. 3.18). The initial steep decline in the plasma drug concentration can be attributed mainly to the combined effect of intravascular mixing and distribution (by passive diffusion) of the drug into tissues and organs of the body. Elimination contributes to a lesser extent to this phase of drug disposition. Once distribution pseudoequilibrium has been established, the rate of decline in plasma concentration decreases and is determined by elimination of the drug from the body. Elimination refers to biotransformation and excretion, i.e., the processes responsible for removal of the drug per se from the body.

It is assumed that a drug introduced directly into the systemic circulation equilibrates very rapidly in the fluids and tissues that compose the central compartment. For many drugs, the central compartment consists of the blood and tissues of highly perfused organs such as lungs, liver, and kidneys. Distribution throughout the remainder of the body space available to the particular drug (peripheral compartment) takes place more slowly. The peripheral (tissue) compartment may be considered to consist of less well perfused tissues such as muscle, skin, and the rumen of cattle and sheep or the colon of horses. The apparent volumes of central and peripheral compartments for a drug depend upon the characteristics of blood flow to their component tissues, partitioning of the drug between blood and tissues (determined by lipid solubility and degree of ionization), and extent of binding to plasma proteins and tissue constituents. An assumption associated with compartmental models is that drug elimination takes place exclusively from the central compartment. Furthermore, distribution and elimination processes associated with the model are assumed to obey first-order kinetics. Accordingly, the rate at which a drug is removed from a compartment is proportional to concentration of the drug in the compartment.

It is usual for drug concentrations in plasma and those organs and tissues that contain a significant fraction of the total amount of drug in the body to decline in a parallel fashion. The linear terminal portion of the disposition curve is appropriately called the elimination phase, and from its slope ($-\beta/2.303$) is derived the half-life of the drug. The extrapolated zero-time intercept of the elimination phase is denoted by the letter *B* and is expressed in units of concentration. Resolving the biexponential disposition curve into its components by the method of residuals (feathering technique) yields a second linear segment called the distribution phase (Rowland and Tozer 1995). The distribution phase has a slope of $-\alpha/2.303$ and a zero-time intercept designated A. If the ordinate of the semilogarithmic graph were in natural logarithms (base e), the slopes of the two exponential phases of the disposition curve would be simply $-\alpha$ and $-\beta$.

The disposition curve is described mathematically by the biexponential equation

$$C = Ae^{-\alpha t} + Be^{-\beta t} \qquad (3.21)$$

where C is the concentration of drug in the plasma at time t (in minutes); A and B are intercept terms with dimensions of concentration (g/mL); α and β are the overall distribution and elimination rate constants, respectively, which are expressed in units of reciprocal time (e.g., min^{-1}); and e represents the base of the natural logarithm. In drug disposition studies the coefficients (A, B) and the rate constants (α, β) are calculated from the experimental data by nonlinear least-squares regression analysis. The sum of A and B gives the initial concentration of drug in the plasma (C_0).

The two-compartment open model (Fig. 3.19) adequately describes the disposition kinetics of most therapeutic agents in humans and animals. Values of the actual pharmacokinetic rate constants (k_{12}, k_{21}, k_{el}) can be calculated from the derived hybrid constants (A, B, α, β) by means of appropriate equations (Riegelman et al. 1968; Baggot 1977). The absorption rate constant after extravascular administration, K_a, can be estimated from the data after determining the hybrid rate constants. Determination of the microconstants permits assessment of the relative contribution of distribution and elimination processes (either or both of which may be altered in disease states or, possibly, by concurrent administration of more than one drug) to disposition of a drug.

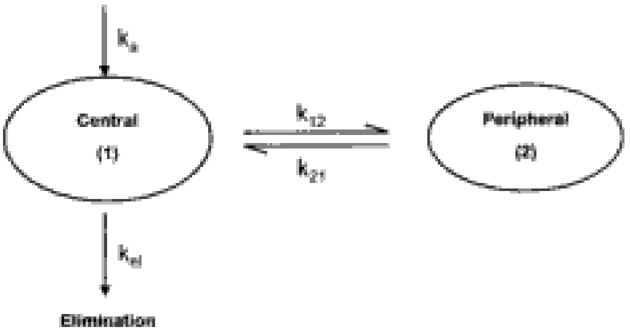

FIG. 3.19—Schematic diagram of the two-compartment open model. The drug is introduced into the central compartment, where it equilibrates almost instantaneously. Distribution between the central and peripheral compartments takes place more slowly; k_{12} and k_{21} are first-order rate constants for drug transfer between the two compartments. Elimination is assumed to take place exclusively from the central compartment; k_a is the absorption rate constant from the extravascular site of administration and k_{el} is the first-order rate constant for drug elimination from the central compartment.

While a biexponential expression describes the plasma concentration-time course of most drugs given by IV injection, the disposition curve for some drugs can be approximated mathematically by the monoexponential equation:

$$C = Be^{-\beta t} \qquad (3.22)$$

where B is the zero-time intercept of the extrapolated first-order decline in the plasma drug concentration with time, and β is the apparent overall elimination rate constant of the drug. The value of B is an estimate of initial concentration of the drug in plasma, based on the premise that pseudodistribution equilibrium is instantly or at least very rapidly attained. Eq. 3.22 can also be applied to describe decline in plasma drug concentration during the postabsorption phase following IM, SC, or oral administration of the drug. When the rate of absorption is slower than the rate of elimination, the decrease in plasma concentrations is governed by the absorption rate, a phenomenon termed *flip-flop* pharmacokinetics.

The pharmacokinetic behavior of drugs that have a high affinity for a particular tissue (perhaps through selective binding) or undergo redistribution is best interpreted according to a three-compartment open model. The following mathematical expression describes the triexponential disposition curve:

$$C = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t} \qquad (3.23)$$

Although the experimental constants (A, B, C, α, β, γ) may be calculated by iterative least-squares linear regression in conjunction with the method of residuals for determining distribution and redistribution phases (termed *curve-stripping*), the best method for determining these constants is to fit the disposition curve by nonlinear least-squares regression analysis. There are indications that the three-compartment open model may be necessary to completely characterize the pharmacokinetic profile of digoxin (Kramer et al. 1974), pentazocine (Vaughan and Beckett 1974), and diazepam (Kaplan et al. 1973) in humans; oxytetracycline in dogs (Baggot et al. 1977); sulfadoxine in horses (Rasmussen et al. 1979); sulfadimethoxine in cattle (Boxenbaum et al. 1977); and gentamicin in various species (Brown and Riviere 1991).

Noncompartmental Analysis. Because artificial, mathematical compartments that have no direct relationship to physiologic spaces within the animal are confusing at times, a method of quantitating the same pharmacokinetic terms that do have physiologic relevance (Vd, Cl, $t_{1/2}$) has been derived. In this approach, called noncompartmental analysis (Martinez 1998), the plasma concentration-time profile or curve is described in terms of slopes, heights, areas, and moments (SHAM). The previous pharmacokinetic equations (Eqs. 3.21, 3.22, 3.23) can be generalized as follows:

$$\mathrm{C} = \sum_{i=1}^{n} C_i e^{-\lambda_i t} \qquad (3.24)$$

where the C_i and λ_i represent the heights and slopes of the n different linear terms that sum together (denoted by the Σ) to describe the plasma concentrations over time t. If one or more of the linear terms describe the appearance (e.g., absorption) of drug in the plasma, the height term is negative (e.g., $-C_i$). The AUC and AUMC are then described as follows:

$$\text{AUC} = \sum_{i=1}^{n} \frac{C_i}{\lambda i} \tag{3.25}$$

$$\text{AUMC} = \sum_{i=1}^{n} \frac{C_i}{\lambda_i^2} \tag{3.26}$$

From these SHAM values, any of the respective half-lives and Vd_{area} can be calculated:

$$\text{Vd}_{\text{area}} = F \cdot \frac{D}{\text{AUC} \cdot \lambda_i} \tag{3.27}$$

Clearance, Vd_{ss}, and bioavailability can be calculated as previously described (Eqs. 3.8, 3.13, and 3.17).

Thus, the vital pharmacokinetic values that can be related to physiologic states or pathologic conditions can be obtained using either compartmental or noncompartmental analysis. The biggest limitation to noncompartmental analysis is that no inference regarding drug localization in the body can be made, whereas compartmental analysis provides understanding of whether drug resides primarily within or outside the plasma and whether more tightly bound drug exists outside the bloodstream in peripheral tissues.

SOME ASPECTS OF DRUG DOSAGE. The term *dose* (D) is simply the amount of drug administered to an animal at any particular time. The term *optimum dose* is a historical term used to estimate the amount of drug that, when administered by a particular route to a certain species, is most likely to produce a certain intensity of response. The desired response is almost invariably a therapeutic effect. Clearly, there is no one optimum dose for every animal, due to the biological variation associated with the pharmacokinetics and pharmacodynamics of the drug from animal to animal. Information obtained from clinical studies lends support to the hypothesis that the intensity of effect produced by a drug is more closely correlated with plasma concentrations of the drug than with dose administered. Simply described, this is because observation of the plasma concentrations has already taken into account much of the variation associated with the pharmacokinetics of the drug. This reflects the situation that exists after pseudodistribution has been attained, in that the tissue drug concentrations and plasma concentrations, although not equal, decline in parallel for most therapeutic agents. The validity of pharmacokinetic predictions based solely on plasma drug concentrations is critically dependent on the assumption that this ratio is relatively constant in any given species.

Knowledge of body clearance of a drug is essential for determining the dosing rate (dose per unit time) that would be required to produce a given average steady-state concentration of the drug (C_{ss}):

$$FD/\tau = C_{ss}\text{Cl}_B \tag{3.28}$$

where F is the fraction of the dose absorbed, D, that enters the systemic circulation intact, and τ is the dosage interval. When the mode of administration is by continuous IV infusion, the right-hand side of Eq. 3.28 gives the infusion rate that will gradually achieve a desired C_{ss} of the drug. Following a period of infusion equal to 3.3 times the half-life of the drug, the plasma concentration will have reached 90% of the eventual steady-state (plateau) concentration.

Drug Administration. Medication may entail administration of a single dose (atropine or morphine when used for preanesthetic medication, thiopental given as an IV bolus dose for induction of anesthesia) or multiple doses at fixed time intervals (chronic dosage of phenytoin and/or phenobarbital for prevention of convulsive seizures, use of digoxin in treatment of congestive heart failure, phenylbutazone therapy for management of lameness in horses, treatment of bacterial infections with antimicrobial agents). The dosing rate of a drug refers to the dose per unit time (dose/dosage interval, or D/τ). When the drug is administered extravascularly, the systemic availability (F) of drug from the dosage form (preparation) administered must be taken into account in calculating a dosing rate.

The most reliable method of drug dosage involves titration by the therapeutic response of the patient, which requires that the intensity of the pharmacologic effect be quantifiable clinically. The continuous IV infusion technique is the best mode of drug administration for allowing adjustment of dose according to response. In antimicrobial therapy, recovery from bacterial infection is the best indicator of effectiveness of treatment. A satisfactory response would indicate that the antimicrobial agent had been given at an appropriate dosing rate and for an adequate duration.

Therapeutic Plasma Concentrations. Major factors that determine concentration of a drug in plasma include the size of the dose and the dosage regimen, formulation of the drug preparation, route of administration, systemic availability of the drug substance and its rate of absorption, extent of distribution and plasma protein binding, and rate of elimination. In addition to these factors, drug accessibility, which usually involves tissue penetration, to the site of action influences concentration attained at the receptor, which along with the affinity and intrinsic activity of the drug for the receptor determines the intensity of response elicited. With an appreciation of factors inherent in quantitatively relating pharmacologic response to plasma concentrations, the value of the plasma drug concentration range for a therapeutic agent (or even for an antimicrobial drug) can be seen in perspective.

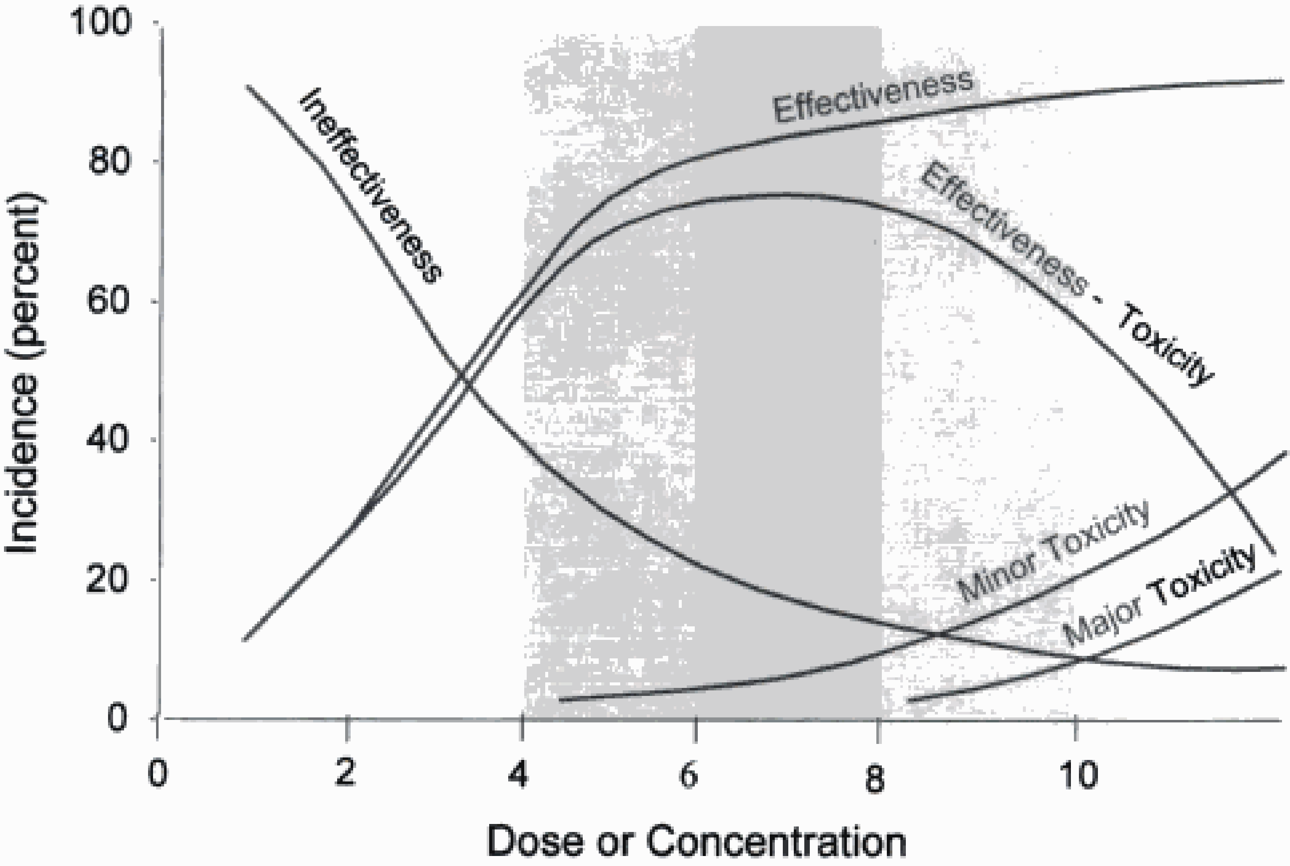

FIG. 3.20—Schematic representation of the incidence (%) of ineffective therapy, effective therapy, minor side effects, serious toxicity, and "therapeutic effectiveness" by dose on plasma concentration. (Adapted from Okita and Archeson 1973.)

TABLE 3.19—Tentative range of therapeutic plasma concentrations and principal pharmacologic effect

Drug	Therapeutic plasma concentrations	Principal pharmacologic effect
	(*μg/mL*)	
Salicylate	25–100	Analgesia
	200–350	Antiarthritic
Acetaminophen	10–30	Analgesia
Pentazocine	0.04–0.16	Analgesia (central)
Phenytoin	10–20	Anticonvulsant, antiarrhythmic
Procainamide	4–10	Antiarrhythmic
Procainamide + *N*-acetyl procainamide	20–30	Antiarrhythmic
Propranolol	0.02–0.08	β-adrenergic blockade, antiarrhythmic
Digoxin	0.6–2.5 (ng/mL)	Positive inotropic, rhythm stabilizer

The therapeutic (safe and effective) range of plasma concentrations for a drug is defined by careful clinical evaluation (which often entails precise physiologic and biochemical measurements) of the response in a sufficient number of appropriately selected individuals. Definition of the therapeutic plasma drug concentration range relies on elucidation of the concentration-effect relationship as well as the concentration-toxicity relationship (Fig. 3.20). As can be seen from the figure, there is a transition from therapeutic concentrations to nontherapeutic concentrations, rather than a clear demarcation between the two. The tentatively accepted range and the principal pharmacologic effect of a variety of drugs are given in Table 3.19. The effective range of concentrations may differ with the therapeutic indication, as with salicylate. The effective concentrations and width of the therapeutic range might be considered to reflect inherent activity and relative safety of a drug respectively. This statement must be interpreted with caution, because chronic administration of some drugs allows tolerance to develop or a side effect to assume prominence. The principles associated with application of the therapeutic concentration range as the basis for establishing the usual dosage regimen are the same for all pharmacological classes of drugs.

Application of Pharmacokinetics to Dosage. Drug disposition studies provide the data necessary for calculating the size of dose that will produce a therapeutic effect for a certain time. The dose (or dose level) in mg/kg represents the product of desired plasma concentration and the apparent specific volume of distribution of the drug (Eq. 3.14). The margin of safety (therapeutic index) and rate of elimination (half-life) of a drug are factors limiting the dose size and duration of action respectively.

Assuming that elimination is first-order and the metabolites are pharmacologically inactive, duration of a therapeutic concentration of a drug, tC_{ther}, is given by

$$tC_{ther} = [\ln(A_0/A_{min})] \cdot t_{1/2} \qquad (3.29)$$

in which A_0 is the dose administered, A_{min} is the minimally effective dose, and $t_{1/2}$ is the apparent elimination half-life of the drug. It follows from Eq. 3.29 that geometric increases in dose (minimum effective dose times 2, 4, 8) produce only linear increases in duration of therapeutic plasma concentrations (half-life times 1, 2, 3, respectively). The longer the half-life of a drug, the longer the duration of drug action for a given dose ratio. The tolerable limit of geometric increases in drug dosage is determined by the dose-related toxicity of a particular drug.

Since effective use of antimicrobial drugs relates to their action on pathogenic microorganisms, both the microbiologic (quantitative susceptibility) and pharmacokinetic properties of these drugs must be considered in calculating dosage (Prescott and Baggot 1993). The potential of an antimicrobial drug to produce adverse effects may vary with the animal species. The success of antimicrobial therapy depends on the attainment of effective drug concentrations at the site of infection. This requires that dosage be appropriate for the drug preparation (pharmaceutical dosage form) selected. Except in severe infections when intravenous administration is required, it is usual to administer antimicrobial drugs by other routes. The route selected (oral, IM or SC injection) depends on the species of animal to be treated and the dosage forms available.

Dosage Regimen. In treating diseased animals, it is usual to administer multiple doses of the therapeutic agent at intervals appropriate for the drug preparation selected. The variables (size of dose and interval between successive doses) are described by the dosage regimen, the objective being to maintain plasma concentrations of the drug within the therapeutic range for the duration of treatment. Such is the case with many kinds of drugs that affect mammalian physiology (e.g., drugs affecting the central and peripheral nervous systems) and some kinds of antimicrobials (compounds such as β-lactam antibiotics which kill bacteria based upon the time that active drug concentrations remain above the minimum inhibitory concentration, or MIC). The C_{max} in the serum or plasma determines the rate of penetration and concentration attained at the active site (Bergan 1978) and can be a critical predictor of efficacy for antibacterial agents that kill bacteria in a concentration-dependent fashion (e.g., aminoglycosides).

In management of disease conditions other than bacterial infections, the first decision is whether to administer a drug. When making this decision, one must recognize that drugs are potentially toxic substances that are likely to produce a therapeutic effect only after correct diagnosis and when administered in proper dosage. Effectiveness of therapy with a drug can be greatly influenced by formulation of the drug preparation (pharmaceutical dosage form). The range of therapeutic plasma concentrations is the only feature of dosage estimation that can be assumed to be constant in different species. Size of the dose depends on apparent volume of distribution, while dosage interval is related to the half-life of the drug. Regardless of the drug dosage form and route of administration, body clearance is the pharmacokinetic parameter that dictates the dosing rate. Since clearance, volume of distribution, and half-life vary among species, it is reasonable to conclude that dosage regimens for most drugs can be expected to vary. The marked differences in dietary habit and digestive system of domestic animals will contribute to variations in bioavailability of drugs from oral preparations.

Steady-State Concentration. Steady state is defined as the time during which concentrations remain stable or consistent from dose to dose. For continuous infusion, steady state is the time during which concentrations plateau; for intermittent dosing, the plasma concentration at steady state fluctuates over time within a dosing interval, but the concentration-time curve is superimposable from interval to interval. True steady state is asymptotically approached as dosing is continued at the same rate, with 90% of steady state achieved after 3.3 apparent elimination half-lives, 95% within 5 apparent elimination half-lives, and 99% within 7 apparent elimination half-lives. As an example, the terminal half-life of desfuroylceftiofur, the active metabolite of ceftiofur, is approximately 10 hours in cattle (Brown et al. 1991). Therefore, concentrations are at approximately 90% of steady state after 33 hours of any particular dosage regimen and are virtually at steady state after the first 3 days of dosing.

The steady-state concentration of a drug can be achieved by various methods of administration. One way is to administer a loading (priming) dose, usually parenterally, and continue with a series of maintenance doses at regular intervals (Fig. 3.21). The loading dose provides an amount of drug in the body that produces an immediate effect, in essence immediately producing steady-state concentrations that are maintained by the maintenance dose. The decision as to whether a course of therapy should be initiated with a loading dose depends on the urgency of treatment and half-life of the drug. For drugs that have a long half-life (digoxin) and for antimicrobial agents that exert a bacteriostatic action (sulfonamides, tetracyclines, chloramphenicol), the loading approach to dosage is desirable. In the case

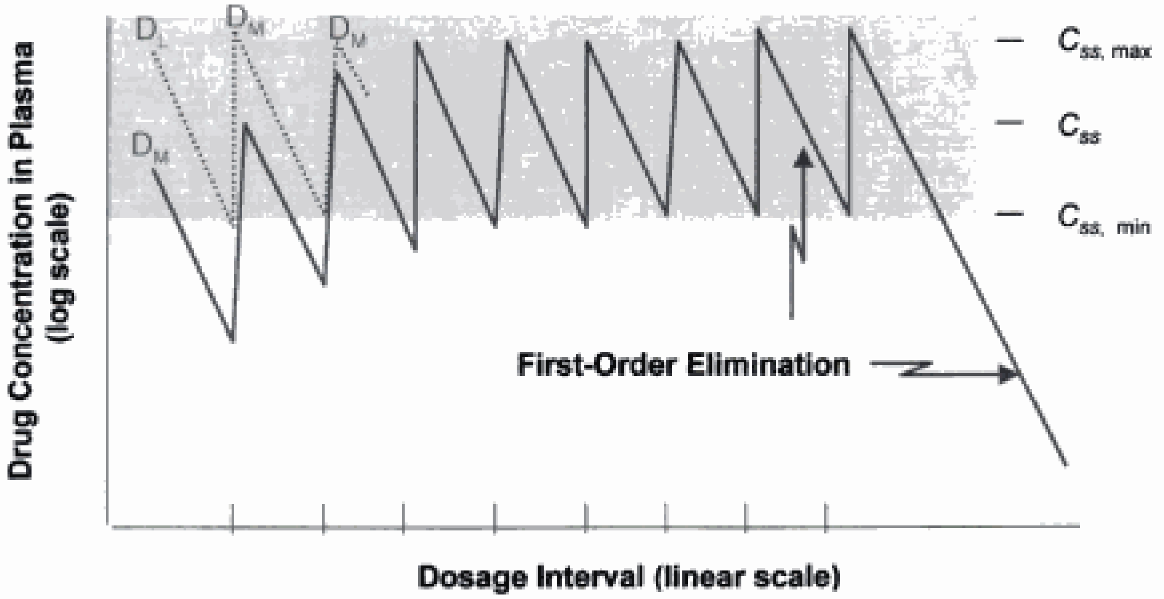

FIG. 3.21—Fluctuation in steady-state plasma concentrations of a drug given at constant intervals. The therapeutic range of plasma drug concentrations is between $C_{ss,min}$ and $C_{ss,max}$. Drug concentrations within the therapeutic range can be achieved either rapidly by giving a loading dose (D_L) or gradually by accumulation through repeated administration of the maintenance dose (D_M). Both methods will yield the same steady-state levels. Upon cessation of dosage, the drug will be eliminated exponentially at the same rate as after administration of a single dose.

of digoxin, which has a narrow margin of safety, the loading dose is given in fractions at short intervals rather than as a single dose. The loading dose (D_L) can be calculated by the following:

$$D_L = (\mathrm{Vd}/F) \cdot C_{ss,max} \qquad (3.30)$$

where D_L is the loading dose and $C_{ss,max}$ is the maximum therapeutic concentration desired at steady state. Typically, a loading dose is not needed unless the interval between doses is much longer than the $t_{1/2}$ and rapid initiation of effective concentrations is required. Pitfalls of a loading dose all relate to rapid achievement of high concentrations and include increased probability of acute toxicities (especially CNS toxicities), inconvenient dosage sizes (volume of injection or number of tablets or capsules), and preclusion of adaptation on the part of the animal to any altered behavioral or cognitive function.

The same steady-state concentration can be achieved gradually by accumulation, without a loading dose (Wagner et al. 1965). This method simply entails administration of a fixed dose repeatedly at constant intervals (the maintenance dose, or D_M). The D_M required to maintain concentrations within the target therapeutic range (i.e., between $C_{ss,max}$ and $C_{ss,min}$) is calculated by the following:

$$D_M = (\mathrm{Vd}/F) \cdot (C_{ss,max} - C_{ss,min}) \qquad (3.31)$$

The interval between D_M required to maintain concentrations within the therapeutic range (T_M) is calculated as

$$T_M = \ln(C_{max}/C_{min}) \cdot t_{1/2} \qquad (3.32)$$

Based on this concept, the average (mean) steady-state plasma concentration of drug, C_{ss}, can be predicted:

$$C_{ss} = (F \cdot D)/(\mathrm{Cl}_B \cdot \tau) \qquad (3.33)$$

where F is the fraction of the dose, D, that enters the systemic circulation intact; Cl_B is body clearance of the drug; and τ is dosage interval. This relationship holds true for any route of administration and pharmacokinetic model, provided absorption, distribution, and elimination of the drug can be described by a set of linear differential equations. By administering fixed doses repeatedly at intervals, each corresponding to the half-life of the drug, a steady-state concentration should be achieved after six doses. To foster owner compliance with drug administration, a dosage interval of 4, 6, 8, 12, or 24 hours, depending on duration of action of the drug, is normally recommended.

A third method of attaining steady-state concentrations of a drug is by continuous IV infusion at a constant rate (zero-order input). The infusion rate, R_0, that will gradually achieve the desired plateau (steady-state) concentration of the drug in plasma is given by

$$R_0 = C_{ss} \cdot \beta \cdot \mathrm{Vd}_{ss} \qquad (3.34)$$

where C_{ss} and Vd_{ss} are the plateau plasma drug concentration and the steady-state volume of distribution, respectively, and β is the overall elimination rate constant of the drug (as defined in Eq. 3.11). The alternate techniques for establishing a plateau concentration are described in the section on drug administration (IV injection). It is sufficient here to say that the plateau can be achieved either rapidly (by simultaneously administering an IV priming dose and starting the infusion) or gradually (by infusing the drug at a constant rate). The magnitude of the plateau plasma concentration depends upon the infusion rate, value of β, and volume of distribution. Since pharmacokinetic terms are constant for a given drug, the rate of infusion determines the plateau concentration. Doubling the infusion rate leads to doubling in magnitude of plateau concentration but does not influence the rate at which plateau concentration is attained. Continuous IV infusion of a drug attains a steady-state at a rate that depends only upon the elimination rate constant (β) or the half-life ($0.693/\beta$) of the drug. After infusing the drug for a period corresponding to four times the half-life, the plasma concentration will be within 90% of the eventual steady-state value. Continuous infusion of a drug that has a narrow margin of safety and short half-life value offers the distinct advantage of control over the steady-state concentration, which remains constant when attained. Upon terminating the infusion, the drug is eliminated by first-order kinetics and at the same rate as that following an IV bolus dose; i.e., the half-life is the same.

Administration of single doses of a drug at specified dosage intervals gives fluctuations in the steady-state concentrations around the average value (Fig. 3.21). The extent of fluctuation may be considered to represent the fraction of the amount of drug in the body that is eliminated during the dosage interval. The value of this term, f_{el}, is given by

$$f_{el} = 1 - e^{-\beta\tau} \tag{3.35}$$

where β is the overall elimination rate constant of the drug and τ is the dosage interval. When the interval between successive doses corresponds to the half-life of the drug, the extent of fluctuation in steady-state concentrations is 50%. A dosage interval of twice the half-life would cause a 75% fluctuation in steady-state plasma concentrations. The wider the fluctuation that is acceptable for a drug, the longer the time (in terms of half-life) that may elapse between successive doses (Baggot 1977). In clinical practice, choice of dosage interval usually represents a compromise between the need for minimizing the extent of fluctuation in steady-state concentrations (based on the therapeutic concentration range of the drug) and the inconvenience of frequent dosing. In veterinary medicine a dosage interval of twice the half-life might be considered suitable for most antimicrobial agents, analgesics, and anticonvulsant drugs. Digoxin, which has a narrow margin of safety, is given to dogs at 24-hour intervals. The half-life of digoxin in normal dogs (mean ± SD, $n = 7$) is 28 ± 4 hours. In azotemic animals the (total) body clearance of the drug is reduced significantly (Gierke et al. 1978). The range of therapeutic serum concentrations is narrow (0.6–2.5 ng/mL), with evidence of toxicity at concentrations exceeding the therapeutic range. Because systemic availability of the drug can vary widely among different oral preparations, the same digoxin product should be used continuously in an animal on maintenance therapy.

Size of the maintenance dose, which replaces the amount of drug eliminated during the preceding interval, depends on the extent of fluctuation and can be calculated in the following manner as well as from Eq. 3.31:

$$D_M = D_L \cdot f_{el} \tag{3.36}$$

When the route of administration is other than IV, an appropriate correction must be made for systemic availability of the drug from the particular dosage form.

INTERSPECIES SCALING. Several approaches exist to adjust drug administration from one animal to another, even from one species to another. These approaches range from adjusting the dose administered by body weight to adjustments based upon detailed information regarding physiologic differences between the animals.

Body Weight. The simplest approach to adjusting drug doses from one animal to another is simply to dose on a body weight basis. This approach will tend to underdose smaller animals and overdose larger animals, due to the more rapid metabolic rate in the former on a body weight basis. However, for most therapeutic agents, the therapeutic margin (range between effective dose and toxic dose) is sufficiently large that such discrepancies are clinically irrelevant.

Body Surface Area. Dosing based on body surface area is a more precise method of scaling drug administration from one animal to another. In general, body surface area increases more gradually than body weight (proportional to volume), a fundamental principle of geometry of 3-dimensional objects (e.g., a 1 cm cube has 1 cm^3 volume and 6 cm^2 surface area, whereas a 2 cm cube, 2 × 2 × 2, has 8 cm^3 volume and 24 cm^2 surface area; volume increases eightfold, whereas surface increases fourfold). Many cancer chemotherapeutics and other drugs with a narrow therapeutic range can be effectively scaled across different body weight individuals within the same species based on body surface area nomograms. Pragmatically, few veterinarians have body surface area nomograms for their patients, and body surface area nomograms are unavailable for many species.

Allometry. For allometric pharmacokinetic scaling across species, pharmacokinetic profiles are described for several different species across a broad range of normal body weights, using a similar type of pharmacokinetic model. Then, the pharmacokinetic parameters of the model are scaled by the following equation:

$$Y = aW^b \tag{3.37}$$

where Y is the pharmacokinetic parameter of interest, W is body weight (usually expressed in kg), and $\log(a)$ and b are the intercept and slope, respectively, obtained from the plot of log(Y) versus log(W). This equation describes a power function.

Allometric scaling is scientifically rooted in the paradigm that metabolism, as well as many other physiologic functions, is normally higher in small mammalian species than in larger mammals (Mordenti 1986). Organ weights, blood flows to organs, heart rate, and cardiac output are larger (when normalized by body weight) in smaller species than in larger species. Since physiologic processes such as these govern drug disposition and elimination, it is entirely rational that drugs highly dependent on organ weight and blood flows can be scaled accordingly. As an example, when evaluated on a time basis, ceftizoxime half-life ranged from less than 15 minutes in the mouse and approximately 20 minutes in the rat to nearly 90 minutes in humans. When the differences in basal metabolic rate were factored in by describing ceftizoxime half-life in heartbeats, all of the species evaluated (mouse, rat, monkey, dog, and human) had 50% of the drug eliminated in approximately 7300 heartbeats (Mordenti 1986) (Fig. 3.22). Jezequel (1994) evaluated fluconazole pharmacokinetics across several species (mouse, rat, guinea pig, rabbit, cat, dog, and human) and reported very strong allometric relationships for Cl_B, Cl_R and elimination half-life (Fig. 3.23). He noted that volume of distribution corrected for body weight was relatively constant across the species, consistent with the notion that time-related pharmacokinetic properties ($t_{1/2}$, Cl_B), rather than time-static pharmacokinetic parameters (volumes), are most altered across species and cannot be simply corrected by normalizing for body weight. Amphotericin B has a similar interspecies scaling profile (Hutchaleelaha et al. 1996).

Using the Food Animal Residue Avoidance Databank, Riviere et al. (1997) evaluated the half-life of 44 veterinary drugs by this allometric method. Eleven of the drugs had half-lives that significantly correlated with interspecies body size. These drugs were mostly antibiotics, and were drugs with primarily renal excretion, drugs in which their metabolism is dependent upon hepatic blood flow rather than enzyme capacity, and low plasma protein binding. Fourteen of the drugs clearly did not have a significant correlation across species, owing to either capacity-limited metabolism and/or high plasma protein binding. The remaining 19 drugs may have had insufficient data to determine a significant relationship, or may not be good candidates for allometric scaling. The general conclusion is that drugs which have low protein binding and are eliminated either by renal mechanisms or by flow-limited metabolism are likely to be scalable across species with the allometric approach.

The physiologic approach to interspecies scaling uses organ weights and organ blood flows to describe a complex hydraulic system which can be tailored to each species. This approach is tremendously useful when concentrations presented to specific organs are important, as is the case with many cancer chemotherapeutic agents. This is a very data-intense approach and does not lend itself to prediction of a pharmacokinetic profile for a new species without substantial organ weight and blood flow data for that new species.

GLOSSARY OF PHARMACOKINETIC TERMS

Primary Pharmacokinetic Terms:

C_p = concentration of drug in the plasma at time t.

$A_B(t)$ = amount of drug in the body at time t.

A, B, C = intercept terms, which represent plasma drug concentrations at time 0, based on the distribution, apparent elimination, and deep tissue elimination phases, respectively, of the disposition curve.

α, β, γ = hybrid rate constants associated with a polyexponential expression that mathematically describes the disposition curve. Values of α, β, and γ are related to slopes of the distribution, apparent elimination, and deep tissue elimination phases, respectively, of the disposition curve; β, the overall elimina-

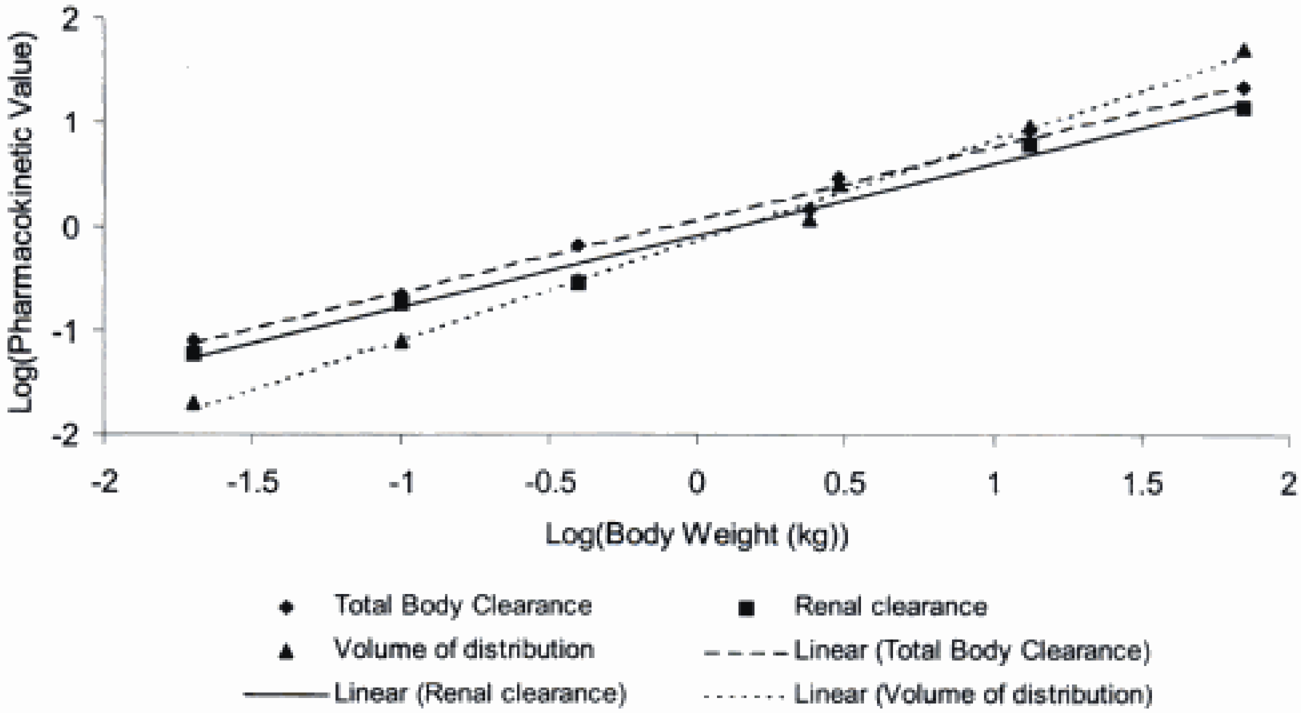

FIG. 3.23—Allometric scaling of volume of distribution (L), total body clearance (mL/min), and renal clearance (mL/min) by body weight (kg). Plotting the logarithm of the pharmacokinetic parameter by the logarithm of body weight linearizes the relationship, the basis of allometric scaling.

tion rate constant, is the negative value of the slope of the linear terminal phase of the plot in C versus time.

C_0 = initial concentration of drug in the plasma following IV injection of a single dose ($C_0 = A + B + C$).

λ_i = general first-order rate constant for the i different exponential phases in a polyexponential predictive mathematical equation that describes the disposition curve.

C_i = general coefficients for the i different exponential phases in a polyexponential predictive mathematical equation that describes the disposition curve.

k_{12}, k_{21} = first-order transfer rate constants for drug distribution between central and peripheral compartments of the two-compartment open model.

k_{el} = first-order rate constant for elimination of a drug from the central compartment.

$t_{1/2}$ = the half-life of a drug (0.693/β), based on first-order (exponential) elimination.

e = base of natural logarithm (ln).

Volume and Clearance Terms:

V_c = apparent volume of central compartment.

Vd = apparent volume of drug distribution; proportionality constant relating plasma concentration of a drug to total amount of drug in the body at any time after pseudodistribution equilibrium has been attained.

Vd_B = apparent volume of distribution obtained by neglecting the α (distribution) phase of drug disposition (extrapolation method).

Vd_{area} = apparent volume of distribution based on total area under the plasma drug concentration versus time curve (area method).

Vd_{ss} = steady-state volume of distribution of a drug.

AUC = total area under the plasma drug concentration versus time curve from $t = 0$ to $t = \infty$ after administration of a single dose.

AUMC = total area under the plasma drug concentration multiplied by time versus time curve from $t = 0$ to $t = \infty$ after administration of a single dose.

Cl_B = body clearance of a drug. This term, which represents total clearance, is the sum of individual clearance processes for the drug. Clearance is expressed as (mL/min)/kg.

Cl_r = renal clearance. This term represents volume of blood cleared of a drug by the kidneys per unit time.

Cl_{nr} = nonrenal clearance. This term represents volume of blood cleared of a drug by other than renal (mainly metabolic) processes per unit time.

f_{ex} = fraction of dose excreted unchanged in the urine.

Terms Associated with Dosage:

D = administered dose.

D_L = loading (or priming) dose.

D_M = maintenance dose.

D/τ = maintenance dose (dosing) rate, i.e., dose per unit time.

τ = dosage interval.

F = systemic availability of a drug, i.e., fraction of the dose that enters systemic circulation intact (unchanged).

f_{el} = fraction of the amount of drug in the body that is eliminated during a dosage interval. This term represents the extent of fluctuation in steady-state concentrations of a drug that takes place during the interval between successive doses.

C_{ther} = therapeutic range of plasma (or serum) drug concentrations.

C_{ss} = plateau (steady-state) concentration of a drug achieved by continuous IV infusion; or average steady-state concentration of a drug in the plasma achieved by a dosage regimen.

C_{max} (or $C_{ss,max}$) = maximum plasma or serum concentration achieved either by a single dose or at steady state.

C_{min} (or $C_{ss,min}$) = minimum plasma or serum concentration achieved prior to a subsequent dose, either prior to or at steady state.

T_M = interval required between maintenance doses to maintain concentrations in the therapeutic range.

R_0 = IV infusion rate.

Terms Associated with Allometry:

Y = pharmacokinetic parameter of interest.

W = body weight (usually in kg).

a,b = antilog of the intercept *(a)*, and the slope *(b)* obtained from the plot of log *(Y)* versus log *(W)*; also known as the power function.

- **Monitoring Response to Therapy**
  - **Therapeutic Drug Monitoring**

Veterinary clinical pharmacology is a clinical science that integrates disease pathophysiology with fundamental concepts of pharmacology to provide a rational basis for drug therapy in animal patients (Davis 1978). In a review of the discipline Brown (1997) stated that the goal of veterinary clinical pharmacology is to apply the principles of pharmacology to more successfully treat patients and to more rationally use medications in veterinary medical practice. In selecting and understanding pharmacologic approaches to the management of diseases, veterinarians must consider the benefits and risks of drug therapy, methods of monitoring responses to therapy, the financial and safety impact of therapeutic decisions, and the impact of the disease process on pharmacokinetics and pharmacodynamics (Coppoc and Stuckey 1977; Novotny 1993a; Wilcke 1986). These concepts shape the principle of rational drug therapy.

RATIONAL DRUG THERAPY. Rational drug therapy is the development and execution of a plan of therapy centered on the pharmacologic and clinical rationale for the selection of drugs to target distinct pathophysiologic processes. Rational drug therapy consists of the selection of the proper drug and dosage regimen appropriate for the species and the disease state in order to normalize bodily functions or to eliminate a pathogen. The decision-making process should be conducted with regard for benefit, risk, and economic considerations and with knowledge of the divergent opinions or controversies frequently associated with approaches to managing certain diseases. The reality of controversy, principally due to insufficient knowledge in drug selection and use for certain diseases, needs to be recognized when striving to optimize therapeutic decisions for individual patients (Ingenito et al. 1992).

A prerequisite to the rational use of any drug is an accurate diagnosis. Diagnoses should be in pathophysiologic terms. For example, one would diagnose streptococcal pneumonia rather than simply pneumonia, nocardial mastitis rather than mastitis, or ascariasis rather than intestinal parasites. Specific pathophysiologic diagnoses lead to specific therapeutic goals. These goals should be established prior to the institution of therapy, and therapy should be monitored against these goals while recognizing and minimizing the undesired effects of drugs (Ingenito et al. 1992).

Rational drug therapy requires a knowledge of the pharmacodynamics and pharmacokinetics of drugs in the species to be treated. Consideration should be given to the relationship between the pathophysiology of the disease and the potential impact of the disease process on pharmacodynamics so that drug effects can be anticipated. For example, sulfonamide antimicrobials competitively inhibit para-aminobenzoic acid (PABA) incorporation into folic acid in bacterial cells, a drug action that may be reversed by an excess of PABA in tissue exudate, necrotic tissue, or purulent wounds (Prescott and Baggot 1993). Similarly, the disease process may alter the drug's pharmacokinetics such that drug absorption, distribution, metabolism, or elimination changes in a predictable or unpredictable manner. Failure to adjust the regimen for the aminoglycoside antibiotic gentamicin in a patient with diminished glomerular filtration could result in drug accumulation and toxicity. Patients should be observed for drug efficacy and toxicity. These observations are needed to determine if therapeutic objectives are attained and will enable a course to be set for continued therapy.

THERAPEUTIC DECISION MAKING. Therapeutic goals are a logical extension of disease pathophysiology. Once established, clear therapeutic goals or end points should guide therapeutic decision making and monitoring therapeutic outcome. The first question to be considered is the need for drug therapy to achieve the therapeutic goals. Once the decision is made that drug therapy is needed, there are several practical considerations surrounding drug selection and the drug of first choice. Detailed below is a problem-solving approach to therapeutic decision making that includes practical considerations of the drug or drugs of choice and a benefit-risk assessment process.

Drug Formulation. When selecting the drug of first choice, available formulations must be considered. Choices may include proprietary formulations, generic products, use of approved veterinary products in an extra-label fashion, human products, or compounding a drug formulation. Often the veterinarian must select from several different formulations or brand name products of the same generic drug product. In other cases no veterinary-approved formulation exists and a human product must be used. Consideration should be given to the approval status when several formulations, including human preparations, are at the veterinarian's disposal. Approved products generally have met regulatory requirements for efficacy and safety in the target animal species for the approved indication and dosage regimen. Such products are produced to high manufacturing standards.

Generic versions of an approved off-patent (pioneer) product are often available to practitioners. Generic drugs are less expensive and may allow practitioners to use certain drugs on a routine basis that otherwise would be very expensive. Generic formulations can differ from a pioneer product in many ways, including the concentration of the active drug and the nature and amount of inactive ingredients (Koritz 1980). A pharmaceutical equivalent is a generic formulation that contains the same amount of active drug but not necessarily the same inactive ingredients as the pioneer reference product. A pharmaceutical alternative is a generic formulation that contains the same active drug but not necessarily the same amount or in combination with the same inactive ingredients as the pioneer reference product. The ultimate test of equivalence of two drug formulations is therapeutic equivalence, or the demonstration of the same pharmacologic effect in the same individual. A more practical comparison is biological equivalence, in which bioequivalence, the rate and extent of drug absorption, is evaluated. Two products are considered bioequivalent when they are equal in the rate and extent to which the active ingredient is absorbed and becomes available at the site of drug action. Regulatory guidelines exist for the design, conduct, statistical analysis, and interpretation of in vivo bioequivalence studies. Typically, key pharmacokinetic variables such as area under the concentration-time curve, maximum plasma drug concentration, and time-to-maximum concentration are compared between the generic and pioneer formulations using a confidence interval statistical analysis. Bioequivalent drugs are generally statistically indistinguishable based on these concentration-time end points (Riviere 1994).

Extra-label use of drugs (ELUD) is any use of a drug product other than in accordance with the directions for use that appear on the label, with the exception that the concurrent use of two approved drugs is not considered an extra-label use unless such concurrent administration is contraindicated by the labeling (Mitchell 1988). The specific ways in which a drug can be used in an extra-label manner include route of administration, dose, duration of therapy, species, indicated disease, or failure to follow the withdrawal period. In the USA, the Animal Drug Use Clarification Act of 1994 provides veterinarians with greater flexibility in extra-label prescribing of certain approved animal drugs and approved human drugs. However, major concerns about ELUD exist, and veterinarians must be selective about using drugs in an extra-label fashion. The chief concern is the potential for drug residues in food products from animals that received drugs in an extra-label manner (Mercer 1990; Sundlof et al. 1986). In general, residue depletion data are not available for the multitude of potential extra-label uses of a drug product. Extra-label use of drugs must occur within the context of a veterinarian-client-patient relationship, and such usage must not result in violative residues in food products from these animals.

A second major concern of ELUD relates to the well-being of the patient and the standards of veterinary practice. For example, penicillin G procaine is an effective antibiotic agent for the treatment of several bacterial diseases but not at the label dose of 6600 units/kg once daily. Rather, doses ranging from 3 to 10 times the label dose are frequently recommended (Plumb 1999). To use 6600 units/kg simply because this is the label dose may result in therapeutic failure.

The US Food and Drug Administration—Center for Veterinary Medicine (US FDA—CVM) restricts extra-label use in certain circumstances, such as when usage practices pose a risk to public health. In 1997, the US FDA—CVM prohibited the extra-label use of fluoroquinolone (e.g., enrofloxacin and sarafloxacin) and glycopeptide (e.g., vancomycin) antimicrobial agents, citing the increasing resistance of zoonotic pathogens in treated animals. Other drugs prohibited from use in food-producing animals are listed in Table 4.1.

Human-labeled drugs are widely used in veterinary medicine, a practice that likely will not change in the future. Many diseases of companion and nonfood animals cannot be treated without the use of human-labeled drugs because appropriate veterinary-labeled drug products often do not exist. Veterinarians have administered cephalexin, diazepam, insulin, lidocaine, morphine, phenobarbital, and antineoplastic agents for many years to companion animals, yet none of these drugs have ever been approved for veterinary use (Reid 1988). As with extra-label use of veterinary-approved drugs, the use of human-labeled drugs in animals raises efficacy and safety concerns, since studies that demonstrate efficacy and safety in domestic animals are lack-

TABLE 4.1—Drugs prohibited by the US FDA—Center for Veterinary Medicine for use in food-producing animals

Chloramphenicol
Clenbuterol
Diethystilbestrol
Dimetridazole
Ipronidazole
Other Nitroimidazoles
Furazolidone (except for approved topical use)
Nitrofurazone (except for approved topical use)
Sulfonamide drugs in lactating dairy cattle (except approved use of sulfadimethoxine, sulfabromomethazine, and sulfaethoxypyridazine)

ing. Potentially harmful and illegal residues following administration of human products to food animals and adverse drug experiences in animals are major safety concerns. Thus, if an appropriate and effective veterinary-labeled product is available, the practitioner should use the approved veterinary product according to label directions. In the absence of a veterinary-labeled product, the veterinarian may consider use of human-labeled drugs, realizing the greater responsibility assumed for the effective and safe use of such products. The human-labeled product should be used only if a veterinarian-client-patient relationship has been established. The practitioner should be reasonably confident that the human product will be safe and effective when administered at the selected dose, route, and duration and for the specific disease. Administration should be consistent with current usage practices and with existing evidence in the veterinary literature on efficacy and safety. Finally, if the use of a human-label product is unavoidable in a food animal species, then adequate measures must be taken to avoid illegal residues in edible products. The veterinarian should be aware of the best available toxicologic, tissue distribution, and tissue depletion data for the drug in the animal species. The veterinarian should provide for an extra-long drug withdrawal period prior to marketing of the animal or animal product for human consumption.

In certain specific instances drug formulations may need to be compounded. Compounding is any manipulation to produce a dosage form of a drug other than manipulations described in the directions for use on the labeling of the drug product. The veterinarian must be aware of efficacy, safety, and legal issues associated with compounding. Safety concerns can range from lack of efficacy, leaving the disease process essentially untreated, to adverse or toxic drug reactions. The mixing of two different drug formulations in the same syringe prior to administration is a form of compounding that could inactivate one or both of the active drug components because of physical or chemical incompatibilities. Drugs in common use that should not be mixed with other drugs in the same syringe or solution include penicillins, cephalosporins, aminoglycosides, tetracyclines, antineoplastic agents, diazepam, and barbiturates (Griffiths 1988). The safety of excipients and vehicles used in compounded formulations may be unknown or they may pose risks if safe usage regimens have not been established in certain domestic animal species. For example, following intravenous administration, propylene glycol, a common vehicle for many drugs, may cause profound adverse cardiovascular reactions, characterized by cardiac asystole, systemic hypotension, and decreased pulmonary and renal arterial blood flow (Gross et al. 1979). The pharmacokinetics and drug depletion for compounded formulations are frequently not known, creating the potential for harmful residues if administered to a food animal species. As a vehicle for compounded drug formulations, dimethyl sulfoxide may contribute to the occurrence of violative drug residues in food products from the treated animals (Mercer 1990).

Dosage Regimen. Once the drug and formulation have been selected, a dosage regimen must be determined. "Dosage" is defined as the determination and regulation of the size, frequency, and number of doses. A "dose" is a quantity to be administered at one time. "Regimen" refers to a systematic course or strictly regulated scheme of treatment. Thus, a "dosage regimen" describes several practical features of therapy, including the dose to be administered, the route of administration, the frequency of administration, and the duration of therapy. Determining a dosage regimen may range from an empirical process to a well-defined process needed to achieve regulatory approval of the drug and regimen. Regulatory approval typically requires adequate and well-controlled studies to characterize the dose-response relationship in the target animal species. The selected dose is then confirmed in laboratory models and in patients during controlled, blinded clinical trials. The randomized, controlled, and blinded clinical trial is recognized as a valuable research method for evaluating new therapies in veterinary patients (Lund et al. 1998). Recently the US FDA—CVM has eliminated the requirement for dose titration studies to identify and select an optimal dosage, but it continues to require pharmaceutical sponsors to demonstrate substantial evidence that a new animal drug is effective and safe for each indication at the proposed dose or dose range (Sundlof 1998). Prudent therapeutic decisions generally include use of approved doses.

The route of drug administration may be limited simply by the available formulation; e.g., tablets, capsules, boluses, and elixirs are designed for oral administration. Suspensions designed for subcutaneous or intramuscular injection generally are not recommended for intravenous administration. The disease process may preclude administration of drugs by certain routes. Vomiting generally precludes oral administration. Severe dehydration may delay absorption of drugs administered subcutaneously. Administration of lidocaine by other than the intravenous route may not effectively control ventricular arrhythmias. When considering administration by a route other than the approved route, one again must consider the efficacy, safety, and legal issues of such extra-label use practices. For example, tilmicosin phosphate (Micotil®) is an effective antimicrobial agent for treating bovine respiratory disease associated with *Pasteurella haemolytica* when administered at the approved dose by the subcutaneous route in cattle. Intravenous injection is fatal (Arrioja-Dechert 1999).

The frequency of dosing is determined by a drug's pharmacokinetics, pharmacodynamics, and demonstrated duration of efficacy. Drugs with brief half-lives, such as lidocaine and dobutamine, may require frequent administration or administration by continuous, intravenous infusion in order to sustain effective drug concentrations at the site of drug action. In contrast, drugs with long half-lives, sustained drug-receptor action, or sustained therapeutic effects require less frequent administration. Aspirin is administered to cats once every 48–72 hours because of the long half-life in this species. The duration of effect of phenoxybenzamine, an irreversible α-receptor blocker used to reduce urethral resistance in cats (Barsanti et al. 1992), is related to the drug's pharmacokinetic properties and the rate of synthesis of new α receptors on the target cell (Hoffman and Lefkowitz 1990). Dexamethasone has a longer anti-inflammatory effect than hydrocortisone, allowing less frequent administration of dexamethasone.

The next step in therapeutic decision making is setting the probable duration of therapy. Many diseases are amenable to a single dose or short-term therapy, while other diseases require days, weeks, or months of therapy, reinforcing the need to understand pathophysiologic processes. With certain drugs the duration of therapy is influenced by the development of tachyphylaxis or receptor down-regulation. With other drugs induction or inhibition of drug metabolic and/or elimination processes accompanies intermediate or prolonged therapy. Prolonged antimicrobial therapy ostensibly contributes to the development of antimicrobial resistance through selection of resistant populations of bacteria (Prescott and Baggot 1993). As with selection of formulation, dose, route, and frequency, the duration of therapy should be determined with careful consideration of the benefits and risks of short-, intermediate-, or long-term therapy.

Well-designed therapeutic regimens (formulation, dose, route, frequency, and duration) may be meaningless should the client fail to comply with prescribed treatment for the patient. In humans certain diseases are associated with compliance failures (Gibaldi 1996). These include illnesses that lack symptoms, such as hypertension; drugs having delayed benefits, such as lipid-lowering treatments; or prophylactic therapy. Veterinary patients that are intractable and cannot be medicated also pose compliance challenges. Types of diseases that encourage compliance are those associated with noticeable and rapid repression of symptoms. Thus compliance improves with therapy of short duration involving simple regimens for which the frequency of dosing is convenient, efficacy is evident, and the drug is associated with a low incidence of adverse drug experiences.

Margin of Drug Safety. The benefit-risk assessment continues with consideration of the relative safety of the drug. For an approved drug, the margin of safety is established during the drug development process with characterization of the toxic features of the drug through evaluation of multiples of the predicted dose using the predicted formulation, frequency, and route in the target species. For other drugs, relative safety may be discerned from usage patterns described in the veterinary pharmacology literature, including reports of adverse drug experiences in animals, or from human applications. Gauging safety through these latter approaches is not a substitute for well-designed target animal safety studies; assumptions regarding cross-species safety may be false. For some drugs the relative safety is low, perhaps with adverse experiences likely even with the use dose in some patients. This does not preclude use of the drug, depending on the severity of the disease and the potential benefit of treatment with the drug. For other, quite safe drugs the precise margin of safety may not be established because assessing a multiple of the use dose may require such high doses to demonstrate an adverse experience that it is impractical and unnecessary. The veterinarian may use these drugs with confidence that adverse experiences are unlikely. Frequently the safety of a drug is refined following regulatory approval and use of the drug in a larger number of patients in the target species.

Contraindications. The next component of risk assessment is consideration of the contraindications for use of the drug and determination of whether any of the contraindications exist in the patient. Contraindications can be characterized as absolute or relative. The severity of the disease and the potential benefit of drug therapy in a specific patient may warrant using a drug when a relative contraindication is present.

Adverse Drug Experiences. Consideration should be given to the likelihood of adverse drug experiences (ADEs) in the patient. An ADE is an unintended or noxious response to a drug that occurs within a reasonable time frame following drug administration (Aronson and Riviere 1989; Davis 1995; Novotny 1993b). Some ADEs are predictable and possibly avoidable; many others are unpredictable. Although any drug potentially can cause an adverse experience, certain drug usage patterns are associated with a higher incidence of ADEs. These include (1) use of human-label drugs in animal patients for which drug safety and efficacy data may be lacking; (2) use of drugs with low therapeutic indices; (3) inappropriate or "trivial" drug use; (4) failure to set therapeutic goals or end points; (5) use of multiple drugs simultaneously in a patient or fixed-dose drug combinations; and (6) failure to weigh the benefits versus the risks of drug therapy. Adverse drug experiences are more likely to occur in younger

Pharmacologic or side effect
Allergic drug reaction
Adverse drug experience resembling allergic reaction
Toxic drug reaction
Idiosyncratic reaction

(pediatric) and older (geriatric) patients, in animals that are obese or emaciated, in pregnant animals, and in animals with diseases of the principal organs of drug metabolism and elimination (liver and kidneys). Modifications in drug disposition patterns in young, old, obese, emaciated, and pregnant patients and during hepatic and renal failure may allow drug accumulation or predisposition to ADEs.

Adverse drug experiences can be classified into six categories (Table 4.2). The first type is lack of efficacy when an appropriate drug is administered at the proper dose, route, interval, and duration to treat a disease for which efficacy previously had been established (based on approved indications or previous clinical experience).

The second category of ADEs is pharmacologic or side effects. These reactions are extensions of the usual pharmacodynamic properties of the drug and, therefore, relate to the mechanism of drug action. For example, α_1-receptor blockers, such as phenothiazine tranquilizers, may cause hypotension as a potential side effect. A gastrointestinal disturbance resulting from overgrowth of nonsusceptible bacteria in patients receiving antimicrobial therapy is a side effect due to suppression of susceptible, normal bacterial flora of the GI tract. Nonsteroidal anti-inflammatory drugs inhibit the enzyme cyclooxygenase and reduce synthesis of prostaglandins that mediate inflammation. As side effects, prostaglandin E_2 and I_2 synthesis by the gastric mucosa and thromboxane A_2 synthesis by platelets are also reduced, resulting in gastric ulcers and decreased platelet aggregation and adhesiveness, respectively. Because pharmacologic or side effects are extensions of the usual pharmacologic response and are often dose related, this form of ADEs frequently can be anticipated and possibly avoided.

The third category of ADEs is allergic drug reactions. Unlike side effects, a first occurrence of this type of ADE cannot be anticipated in a patient. Further, allergic drug reactions are not dose related. Clinical manifestations of allergic drug reactions follow known allergic patterns and range from mild skin reactions to anaphylaxis. Other types of drug allergy include skin eruptions, serum sickness–like (type III) reactions, hemolytic anemia, thrombocytopenia, allergic gastroenteritis, and systemic lupus erythematosis (SLE). The usual mechanism of allergic drug reactions consists of the drug or a drug metabolite forming a covalent bond with an endogenous substance, resulting in an allergen. Because some drugs have common structures or metabolites, cross-reactivity between different drugs can occur. For example, patients allergic to one penicillin may be allergic to most penicillins. Cephalosporins share the β-lactam structure with penicillins, and although the incidence in animals is not known, as many as 20% of humans allergic to penicillins demonstrate cross-reactivity to cephalosporins (Mandell and Petri 1996). However, a much smaller percentage of these people will manifest clinical signs of an allergic reaction to cephalosporins.

The fourth type of ADEs includes reactions that resemble allergic reactions but do not have an immunological basis. These reactions might consist of cardiovascular or pulmonary effects such as those manifested following rapid intravenous administration of certain drugs dissolved in a polyethylene glycol vehicle (Gross et al. 1979). Hematologic reactions that resemble autoimmune hemolytic anemia but lack an immunological basis may occur following intravenous administration of dimethyl sulfoxide if the concentration is greater than 20% (Jenkins 1985). Drug fever, or hyperpyrexia, also is included in this category. Hyperpyrexia induced by acetylsalicylic acid (aspirin) is believed to stem from uncoupling of oxidative phosphorylation at the cellular level by salicylate (Riviere 1985).

Toxic drug reactions represent the fifth category of ADEs. Direct organ damage occurs through complex mechanisms that, in general, are not related to the pharmacologic effects of the drug. For example, the nephrotoxic effects of aminoglycoside and outdated tetracycline antimicrobial agents have no relationship to the binding of these drugs to bacterial ribosomal subunits and the decreasing bacterial protein synthesis that results in an antimicrobial effect. Similarly, the hepatotoxic effects of acetaminophen are mediated through reactive drug intermediates that have no bearing on the antipyrexic and analgesic properties of the drug.

The final category of ADEs comprises the idiosyncratic or unexpected reactions in an individual animal that cannot be classified in the previous five categories. The term applies to unusual effects of a drug that occur in a small percentage of the patient population and, like allergic drug reactions, are unrelated to drug dose. Often idiosyncratic reactions have a genetic basis.

Recognition of ADEs can be challenging, especially when the manifestations of an ADE resemble the disease the drug is being used to manage. For example, aspirin may be used to manage pain, inflammation, and pyrexia, yet the drug has the potential to induce fever. If most of the other disease symptoms of a patient receiving aspirin are ameliorated, yet pyrexia presents, drug fever should be suspected. With most ADEs, a definable temporal relationship exists between drug administration and manifestation of the adverse experience. However, this may be seconds, minutes, hours, days, or even weeks, as is possible with hemolytic anemia or SLE-like reactions. An ADE usually improves with discontinued drug administration. When reoccurrence is expected with repeated administration, the risk of reinstituting therapy with the offending drug must be weighed against the benefits of therapy with the drug.

An ADE initially manifested as a minor skin rash may, upon subsequent use, result in more severe reactions.

Managing ADEs can be equally challenging (Davis 1995, 1989). General principles of managing ADEs include (1) providing life support where appropriate (e.g., for anaphylactic reactions); (2) ceasing therapy with or modifying dosage of the offending drug; (3) selecting an alternative drug should therapy continue to be required; (4) enhancing drug elimination; (5) where available and appropriate, administering specific antagonists or antidotes; and (6) managing organ (e.g., liver, kidney) toxicity using strategies similar to those used to treat such toxicity from other causes. Mild, acute hypersensitivity reactions may be managed by allowing time for clearance of the offending drug. In other cases, such as hemolytic anemia or SLE-like reactions, immunomodulation may be required. Epinephrine is the drug of choice for treating anaphylaxis, owing to the effects of epinephrine on vascular α_1 receptors (causing vasoconstriction and supporting blood pressure), cardiac β_1 receptors (causing positive inotropic and chronotropic effects and supporting cardiac output), and respiratory β_2 receptors (causing bronchodilation and supporting ventilation). Corticosteroids and antihistamines are of lesser clinical value in anaphylaxis but may be useful in managing less severe allergic drug reactions.

Preventing ADEs is also a challenge. Allergic and idiosyncratic reactions are unpredictable. Once a reaction is observed in a patient, the reaction should be recorded and efforts undertaken to guard against repeated administration of the offending drug to the patient. Additional measures to prevent ADEs include (1) cautious use of human-label drugs until safety and efficacy of specific products become established in veterinary patients; (2) avoidance of polypharmacy (refer to section on drug interactions) and fixed-dose drug combination products; (3) setting of clear therapeutic goals and end points; and (4) assessing the benefit-risk aspects of drug therapy. Potential ADEs frequently are detected during drug development. However, in many instances ADEs are not noted until postapproval use in the larger target animal population. Adverse experiences may be general to a class of drugs or specific to a member of a drug class. Adverse experiences also may be specific to a domestic animal species or even to subpopulations within a species. When ADEs are suspected, an attempt should be made to determine the probable association between the drug and the ADE and to characterize the ADE. Suspected ADEs may be reported to the drug sponsor or the drug regulatory authorities (e.g., US FDA—CVM). Suspected ADEs are listed in product monographs at the time of drug approval, and those reported to the US FDA—CVM are published annually (Grassie 1997).

Drug Interactions. Frequently, concurrent administration of more than one drug is needed to achieve therapeutic goals. In these circumstances the potential for drug interactions becomes part of risk assessment. A drug interaction is the change in magnitude of the pharmacologic effect of a drug due to some other factor (Griffiths 1988). The other factor may be another drug, the focus of this discussion. However, drug vehicles, food, nutrients, plastic components of syringes or intravenous infusion sets, and environmental chemicals are among the factors that potentially impact the pharmacologic effect of drug. Drug interactions may occur in vitro when incompatible drugs are mixed in the same syringe or vial or when drugs are mixed in incompatible solvents. For example, solutions of the following drug pairs are incompatible: epinephrine and sodium bicarbonate, gentamicin and carbenicillin, ketamine and barbiturates, and methylprednisolone sodium succinate and calcium gluconate (Trepanier 1994). Types of in vitro reactions that can occur from mixing these drugs include hydrolysis, oxidation, reduction, complexation, acid-base reactions (incompatible pH), and precipitation (Paul 1987). In vivo drug interactions may result in diminished or enhanced drug effects, expression of a new or different effect, or perhaps no obvious pharmacodynamic change but altered pharmacokinetics that may not be clinically apparent. Some drug interactions are advantageous and are exploited in therapy. Many others are potentially deleterious. A documented or potential drug interaction is rarely an absolute contraindication for concurrent administration and hence becomes a component of risk assessment in therapeutic decision making.

Most drug interactions of clinical significance result in changes in pharmacokinetics. These include changes in absorption, distribution, metabolism, or excretion of a drug as a result of concurrent administration of a second drug. Cimetidine or other H_2-receptor antagonists alter gastric pH and may affect absorption of other drugs across the gastric mucosa. Drugs such as metoclopramide, anticholinergic agents, and sympathomimetics alter gastric emptying and delivery of other drugs to the small intestine, which is the site of adsorption of most orally administered drugs. Hence the rate of absorption of other drugs may be altered by agents that alter gastric emptying. Competition between drugs for binding to plasma proteins may alter drug distribution and transiently increase free plasma drug concentrations. Clearance of the drug also is likely to change; however, an adverse drug experience may occur should one or both of the interacting drugs have a low therapeutic index. Changes in hepatic drug metabolism can occur with certain drugs, leading to enzyme induction or inhibition. A drug that induces hepatic enzyme activity may increase clearance of itself and other drugs administered concurrently, thus reducing drug efficacy. Enzyme induction takes time to occur but may persist for several days, weeks, or months after withdrawal of the inducing agent. Hepatic enzyme inhibition generally develops quickly after administering the inhibiting drug and similarly reverses quickly upon withdrawal of the drug. A drug that inhibits hepatic enzyme activity may decrease clearance of other drugs administered concurrently, thus increasing the potential for adverse or toxic drug experiences. Drugs that alter hepatic blood flow (e.g., propranolol) may also limit clearance of a second drug should the later drug normally be efficiently extracted from plasma by the liver.

While there are few examples of specific drug interactions stemming from altered glomerular filtration, any drug that may alter hemodynamics and renal blood flow may interact with the elimination of a second drug that is chiefly dependent on glomerular filtration for elimination. Tubular secretion may be inhibited competitively by drugs that compete for the same transport mechanism. Tubular reabsorption of a drug may be altered by a second drug that changes urine pH or urine flow rate.

Changes that occur in pharmacodynamics stemming from concurrent administration of two drugs might be predicted from the mechanisms of drug action. Two drugs may have additive or antagonistic effects on the same drug receptor. Alternatively, physiologic additive or antagonistic actions may occur through independent effects on receptors associated with antagonistic arms of physiologic processes, as might occur through simultaneous effects of one drug on the parasympathetic nervous system and of a second drug on the sympathetic nervous system. Synergism occurs when the pharmacologic effect of the interaction exceeds additive effects that might be predicted from concurrent administration. Synergism is frequently leveraged in the treatment of bacterial infections through combination antimicrobial therapy with a penicillin and an aminoglycoside or use of a potentiated sulfonamide (Stowe 1984).

While there are many potential adverse drug interactions, drugs with narrow therapeutic indices are more likely to be associated with interactions that result in diminished, enhanced, or toxic drug effects. Under such circumstances adjustments in the dosage regimens may be appropriate.

DRUG THERAPY IN SPECIAL PATIENT POPULATIONS

Drug Therapy during Pregnancy. Pregnancy poses a number of challenges for designing rational therapeutic strategies because the potential benefits of therapy to the dam must be balanced against the potential risks to the embryo or fetus (Murray and Seger 1994). Relatively few drugs are specifically approved for or have demonstrated safety in pregnant animals. Changes in physiology from the nonpregnant state include increased gastric pH, decreased GI motility, decreased plasma protein binding of drugs, increased cardiac output, and progesterone-mediated induction of hepatic biotransformation. These differences in physiology potentially affect absorption, distribution, metabolism, and elimination of drugs administered to pregnant animals. When treating pregnant animals, one must prevent teratogenic or other possible adverse effects on the developing embryo or fetus. The factors that most affect placental transfer of drug, and thus exposure of the fetus to drugs administered to the dam, are the dose of the drug, frequency of drug administration, volume of distribution, extent of plasma protein binding, clearance in the dam, blood flow to the placenta, drug metabolism by the placenta, and the rate of drug diffusion across the placenta. Of these, the drug diffusion rate is the most important factor and is dependent upon the concentration difference between maternal and fetal plasma, the surface area for diffusion, and the drug's lipid solubility. Because maternal fluids are slightly more alkaline than fetal fluids, basic drugs, such as atropine, epinephrine, propranolol, quinidine, erythromycin, and trimethoprim, have a tendency to concentrate in fetal plasma. Acidic drugs, such as penicillin, aspirin, furosemide, and phenobarbital, diffuse slowly across the placenta.

In addition to teratogenic effects, other potential adverse effects include prevention of implantation and early termination of pregnancy, mutagenesis, and fetal growth retardation. Later in pregnancy, drug effects in the fetus may be manifestations of the pharmacodynamics of the drug. Predicting the fetal toxicant nature of a particular drug in the absence of data supporting safety during all stages of pregnancy is difficult. When selecting drugs for use in pregnant animals, consideration should be given first to drugs specifically approved for use and with demonstrated safety in pregnant animals of the species. For other drugs a conservative and prudent approach is to regard such drugs as potential development toxicants. Papich and Davis (1986) and Murray and Seger (1994) reviewed relative risks in pregnancy of a large number of drugs in common use in veterinary and human medicine, respectively. These reviews are useful when considering options for treating pregnant animals with drugs that have not been evaluated specifically for safety during pregnancy in the target species.

Drug Therapy in Neonatal and Pediatric Patients. As with treating pregnant animals, drug therapy in neonatal and pediatric patients poses unique challenges. Few drugs are specifically approved for young animals, and physiologic differences from adults of the species lead to important differences in drug disposition. Following topical administration, the rate and extent of drug absorption are enhanced due to an immature barrier to percutaneous absorption (Besunder et al. 1988). Absorption from the GI tract may be affected by variable gastric emptying rates, irregular peristalsis, and increased permeability of the intestinal mucosa during the neonatal period (Papich and Davis 1986; Besunder et al. 1988). The volume of distribution of most drugs is greater in neonates due to proportionally greater body water content, particularly extracellular fluid volume, and decreased plasma protein binding due, in part, to lower plasma albumin concentrations in neonates. Further, full development of the blood-brain barrier may not be complete during the first few days postpartum, facilitating distribution of drugs to the central nervous system that otherwise would be restricted from it (Short 1984). The proportionally lower amount of adipose tissue in neonates limits drug sequestering in or redistribution to adipose, a process important in terminating the effects of short-acting thiobarbiturate anesthetic agents (Branson and Booth 1995).

Although species differences exist, hepatic biotransformation mechanisms are relatively immature in neonates. Biotransformation processes mature within a few days postpartum in foals but may take 3–6 weeks in other domestic animal species (Papich and Davis 1986; Short 1984). Glomerular filtration by the kidneys appears limiting only during the first few days postpartum. However, tubular secretion, important for elimination of many acidic or basic drugs, may take 3–4 weeks to fully develop (Short 1984). Applying dosage regimens designed for mature animals to neonatal and pediatric patients may result in drug accumulation due to differences in drug disposition and adverse or toxic drug reactions. In other situations, drugs safe in mature animals are inherently unsafe or potentially toxic in young animals. Examples of the latter drugs include the antimicrobial agents tetracyclines, sulfonamides, and fluoroquinolones. Based on known differences in drug disposition patterns in young animals, it may be possible to adjust adult dosage regimens to minimize the risk of adverse experiences in young animals. For example, aminoglycoside antibiotics may be safe and effective in neonates if the dose and dosing interval are both increased to account for the larger volume of distribution (Wilcke 1991) and reduced renal clearance.

Drug Therapy in Geriatric Patients. As with pediatric patients, tailoring drug therapy to the individual takes on great importance in geriatric patients. Among animals within a species the aging process can proceed at different rates, as is seen among different breeds of dogs. Older animals are more likely than younger animals to receive multiple drugs to manage diseases of a more chronic nature. Aging results in physiologic changes that potentially alter drug disposition and may lead to enhanced or toxic drug effects. Although information on specific age-related changes in drug disposition in domestic animals is scarce, qualitative predictions of effects of aging on drug absorption, distribution, metabolism, and elimination can be based on general knowledge of age-related physiologic changes.

With age, gastric pH is increased, gastric emptying is prolonged, and GI motility is weakened (Ritschel 1987). The consequences of these physiologic changes may include a delay in disintegration of tablets and capsules, alteration of the degree of drug ionization, and decreased mixing of GI contents, causing slower dissolution of orally administered drugs. Prolonged gastric emptying may delay transit of drugs from the stomach to the small intestine, the site of absorption of most orally administered drugs. The surface for absorption from the GI tract also decreases with age as macrovilli and microvilli atrophy. The sum effect of these physiologic changes may be a decrease in the rate of drug absorption with lesser or no effect on the extent of absorption.

With age lean body mass decreases as the proportion of adipose tissue increases and total body water decreases. The volume of distribution of lipid-soluble drugs may increase, thus prolonging half-life. It is likely that drug distribution into body fat does not correspond to distribution to the desired site of action for most drugs. Thus efficacy could be diminished (Aucoin 1989). In contrast, water-soluble drugs will exhibit a smaller volume of distribution (Ritschel 1987). Also potentially affecting volume of distribution is a reduction in plasma albumin concentration and a decrease in the amount of drug bound to plasma protein. For drugs highly bound to albumin, the proportion of free drug may increase, leading to more drug available for interacting with receptors and augmenting the intensity of drug action or leading to adverse or toxic effects.

Drug metabolism consists of biotransformation of drugs to more polar compounds. Metabolism generally occurs in the liver; however, biotransformation can occur in the kidneys, other tissues, and plasma. The effects of aging on drug metabolism appear minimal. Reduction in hepatic blood flow, which occurs with aging, decreases biotransformation of drugs whose hepatic metabolic rate is blood flow dependent, as discussed in the next section (Ritschel 1987; Aucoin 1989).

The greatest difference in drug disposition between older and younger patients is the rate of drug elimination (Reidenberg 1987). Functional renal mass and the number of functional nephrons decrease with age. This leads to a reduction in effective renal plasma flow and glomerular filtration rate (Ritschel 1987). These aging changes in renal function, analogous to changes observed in patients with chronic renal failure, lead to a decrease in the rate of elimination of drugs and drug metabolites normally excreted by the kidneys (see below).

Drug Therapy in Patients with Liver Failure. With reduction in hepatic blood flow, drugs with blood-flow-limited hepatic metabolism may accumulate. Although the content and activity of both phase I and phase II liver enzymes decrease, hepatic metabolism of drugs is probably not overwhelmed until an extreme loss (greater than 80%) of liver function has occurred. No adequate routine biochemical test exists that correlates with hepatic drug metabolism, and thus close patient monitoring is needed for evidence of drug toxicity. Many drugs in common use are well tolerated in patients with hepatic dysfunction. In general, β-lactam antimicrobial agents are safe, whereas lincosamides, macrolides, sulfonamides, and chloramphenicol are best avoided in hepatic-failure patients (Bunch 1995; Tams 1984). The glucocorticoids prednisone and cortisone require reduction of the keto group at C-11 by hepatic enzymes before these drugs are biologically active (Chastain and Ganjam 1986) and are best avoided in advanced hepatic insufficiency. Prednisolone and hydrocortisone are suitable alternatives, whereas long-acting glucocorticoids are generally avoided unless potential benefits outweigh the risks of prolonged half-lives.

Drug Therapy in Patients with Renal Failure. In relation to drug therapy, the most profound changes in drug disposition accompany renal failure. With age, functioning nephron mass diminishes, as does tubular secretion and the ability to concentrate and acidify urine. Chronic renal failure is common in aging animals. Drug disposition changes associated with chronic renal failure include diminished clearance of drug excreted by the kidneys and alterations in drug distribution patterns. With uremia, protein binding and hepatic biotransformation of some drugs are decreased. Hence drugs that normally are excreted by the kidneys may accumulate, increasing the risk of ADEs. Drugs such as aminoglycosides that are nephrotoxic and undergo renal elimination have enhanced nephrotoxic potential. Thus, nephrotoxic drugs should be avoided in patients with chronic renal failure. Further, drugs requiring renal excretion should be avoided unless accumulation is relatively innocuous. Alternatively, to compensate for decreased clearance, formulas for adjusting the drug dose, dosing interval, or both may be applied to drugs that may accumulate in renal failure (Papich 1995; Polzin et al. 2000). These formulas are based on the reduction of glomerular filtration rate, generally estimated from a reduction in creatinine clearance in chronic renal failure. For some drugs plasma concentrations may be measured readily in the clinical setting through therapeutic drug-monitoring programs, with dosage adjustments based on established safe and effective plasma drug concentrations (see below).

MONITORING RESPONSE TO THERAPY. A final and important consideration in designing drug therapy is establishing a priori what end points, and changes in those end points, will be monitored to assess response to therapy (Coppoc and Stuckey 1977; Novotny 1993a). Plans should be established to evaluate the results of theory. Variables should be monitored to determine whether the animal is responding to treatment. Criteria should be established for what constitutes a "cure" or for concluding there is a lack of a therapeutic response. The clinician should determine when an initial response to therapy might occur. Consideration should be given also to follow-up procedures and alternative therapeutic strategies.

For many diseases the end points for monitoring therapeutic response may be simple clinical observations. For other diseases monitoring may include responses seen in clinical pathology variables or radiographic findings. Monitoring end points in chronic diseases of older patients is particularly important and challenging, as follow-up care may be forgotten, prescriptions may not be filled, enthusiasm, compliance, and vigilance may wane, and economic factors may limit what the client is willing and able to provide for the animal (Kay 1994).

Therapeutic Drug Monitoring. Therapeutic drug monitoring (TDM) can provide the practitioner with information useful in tailoring drug therapy to the individual patient. A clinical need for TDM may arise from a lack of therapeutic response, suspected drug toxicity, or the desire to confirm a therapeutic approach. Therapeutic drug monitoring of plasma (or serum) is the quantification of either the free or the total plasma concentration of drug to assess whether a particular patient has attained subtherapeutic, therapeutic, or toxic plasma concentrations (Neff-Davis 1988). Generally, drugs have a characteristic plasma concentration–response relationship, and clinical response correlates better with plasma concentrations than with the administered dosage (Jernigan 1991). Much of the variability in pharmacokinetics (drug absorption, distribution, metabolism, and elimination) between animals is reflected in plasma drug concentrations for any given dose administered. Insight into the effect of a disease process on pharmacokinetics may be gleaned from knowledge of the plasma concentration profile of the drug.

Limitations of TDM in veterinary medicine restrict its practical application to only a few drugs at present (Papich 1991). Therapeutically effective plasma concentrations must be defined. Similarly, plasma concentrations that are subtherapeutic or toxic need to be established. A cost-effective, clinically applicable method for analyzing the plasma (or serum) concentration of the drug must be available, and for some drugs, the results of the analysis should be available prior to administering the next dose to a patient so that dosage adjustments may be made. For drugs applied topically or that have transient effects, there is no value in measuring plasma concentrations. For drugs with minimum interpatient variability in drug absorption, distribution, metabolism, and elimination, it is less likely that the optimum dosage regimen differs much between patients.

Thus, TDM is of value when a drug assay is available in the clinical setting, therapeutic and toxic drug concentrations are known, the pharmacologic effect is proportional to the plasma drug concentration, and pharmacokinetic properties in the species are well characterized, with significant interpatient variability in pharmacokinetics (Papich 1991). Drugs that have been monitored in veterinary medicine include the cardiac glycoside digoxin, the anticonvulsant phenobarbital, methylxanthines (e.g., aminophylline, theophylline), cardiac antiarrhythmic agents such as lidocaine and procainamide, and antimicrobial agents. Of the latter, TDM is particularly useful for monitoring plasma concentrations of aminoglycoside antibiotics (e.g., gentamicin, amikacin), as these drugs have a low therapeutic index, and pharmacokinetics can be quite variable between patients. For drugs with small therapeutic indices, TDM can aid in optimizing dosage regimens to maximize benefits and minimize risk. While TDM is a valuable tool that increases the likelihood of therapeutic success, TDM will not replace the clinician's good judgment or good observational skills in monitoring response to therapy (Jernigan 1991).

Primary diseases of the autonomic nervous system are infrequently encountered in domestic animals, and yet drugs that alter autonomic activity are used daily in the clinical practice of veterinary medicine. Physiologic functions of diseased organs often are still responsive to their nervous supply and may favorably respond to drugs that induce autonomic effects. Also, autonomic blocking drugs are often used prior to anesthesia to prevent inadvertent stimulation of autonomic influences on visceral tissues and, furthermore, certain autonomic drugs are life-saving antidotes to particular types of chemical intoxicants.

It is obvious, therefore, that a thorough comprehension of autonomic pharmacology is required for a rational approach to therapeutic management of a wide variety of clinical disorders in animals.

ORGANIZATION OF THE AUTONOMIC NERVOUS SYSTEM. The autonomic nervous system is a peripheral complex of nerves, plexuses, and ganglia that are organized to modulate the involuntary activity of secretory glands, smooth muscles, and visceral organs. This system functions to sustain homeostatic conditions during periods of reduced physical and emotional activity and, equally important, to assist in internal bodily reactions to stressful circumstances. The autonomic nervous system also has been termed the visceral, involuntary, or vegetative nervous system.

In relation to clinical pharmacology, the most important components of the autonomic nervous system are the outflow (efferent) nerve tracts. Efferent autonomic tracts supply motor innervation to visceral structures. The efferent segment of the autonomic nervous system is divided into two principal components: the sympathetic nervous system and the parasympathetic nervous system. Sympathetic and parasympathetic outflow tracts comprise preganglionic neurons and postganglionic neurons. The cell body of a preganglionic neuron is located within the central nervous system (CNS). The synapse (junction) of a preganglionic axon with a ganglionic neuronal body occurs outside the CNS within an autonomic ganglion. An axon of a ganglionic cell passes peripherally and innervates its effector organ or organ substructure. The junction of a postganglionic axonal terminal with its effector cell is termed a neuroeffector junction.

Sympathetic Nervous System. The sympathetic nervous system is often synonymously referred to as the thoracolumbar outflow because of its anatomic origin (Fig. 5.1). Sympathetic preganglionic fibers (axons) originate from cell bodies localized within the intermediolateral columns of the thoracic and lumbar regions of the spinal cord. These fibers are myelinated; they exit the spinal cord with the ventral (anterior) nerve roots and then form bundles (white rami communicantes) before entry into the paravertebral chain of sympathetic ganglia. Gray rami communicantes are composed of nonmyelinated postganglionic fibers that exit the sympathetic chain and reenter spinal nerve roots to be distributed to target structures (sweat glands, blood vessels, hair follicles) within the limbs and body trunk.

Paravertebral (or vertebral) ganglia are located bilaterally to the ventral aspects of the vertebral column. Ganglia on each side are interconnected by nerve fibers to form sympathetic ganglionic chains that extend into the cervical and sacral regions; however, ganglia in these areas receive fibers only from the thoracolumbar spinal cord.

Upon entering the sympathetic ganglionic chain, a preganglionic fiber may terminate in one of several manners. It may synapse with a neuronal body located within the immediately adjacent ganglion, it may ascend or descend the sympathetic chain and synapse with a neuron of a distant ganglion, or it may pass through the chain and synapse in a prevertebral ganglion rather than in the vertebral chain. Prevertebral ganglia are located more peripherally than the vertebral chain and include the celiac, cranial (anterior) mesenteric, and caudal (posterior) mesenteric ganglia. They supply fibers to abdominal and pelvic viscera. Sympathetic control to the head and neck arises from cranial (anterior, or superior), middle, and caudal (posterior, or inferior) cervical ganglia. Fibers from the cervical ganglia and the anterior thoracic ganglia innervate the thoracic organs.

Sympathetic postganglionic fibers are usually relatively long since most sympathetic ganglia are located in close proximity to the spinal cord (Fig. 5.1). Sympathetic preganglionic fibers may ramify, form plexuses, and subsequently synapse with numerous different postganglionic cell bodies. Furthermore, one sympathetic ganglionic neuron may be innervated by preganglionic fibers originating from several different nerve bodies. Sympathetic discharge may, therefore, affect several different target organs and organ substructures.

The adrenal medulla is an extremely important component of the sympathetic nervous system. It is embryologically and functionally homologous to a sympathetic ganglion but does not contain postsynaptic neuronal cells. Instead, secretory chromaffin cells are present. They are innervated by typical preganglionic fibers that issue from the midthoracic spinal cord. Adrenal chromaffin cells contain epinephrine and norepinephrine; these hormonal substances are released from the adrenal gland into the circulatory system.

Parasympathetic Nervous System. Parasympathetic outflow tracts originate from the midbrain, medulla oblongata, and sacral spinal cord (Fig. 5.2). The parasympathetic component of the autonomic nervous system is referred to anatomically as the craniosacral outflow.

The vagus nerve (the 10th cranial nerve) is the most important parasympathetic nerve trunk. It arises from the medulla oblongata and sends efferent fibers to all thoracic and abdominal viscera from the caudal pharyngeal region to the cranial portions of the large colon. Fibers from the spinal accessory nerve (11th cranial nerve) may also join the vagus trunk. The facial (7th cranial nerve) and glossopharyngeal (9th cranial nerve) nerves arise from the medulla oblongata and carry parasympathetic fibers to various glands and smooth muscles within the head. The oculomotor nerve (3rd cranial nerve) carries preganglionic efferent fibers from the Edinger-Westphal nucleus of the midbrain to the ciliary ganglion that then supplies postganglionic autonomic motor fibers to ocular structures.

The sacral portion of the parasympathetic system comprises nerve fibers arising from the sacral spinal cord. These fibers form the pelvic nerves; they terminate in ganglion cells located in the colon, bladder, and sex organs.

Parasympathetic ganglia are localized more peripherally than sympathetic ganglia and usually are close to innervated structures. In many cases, parasympathetic

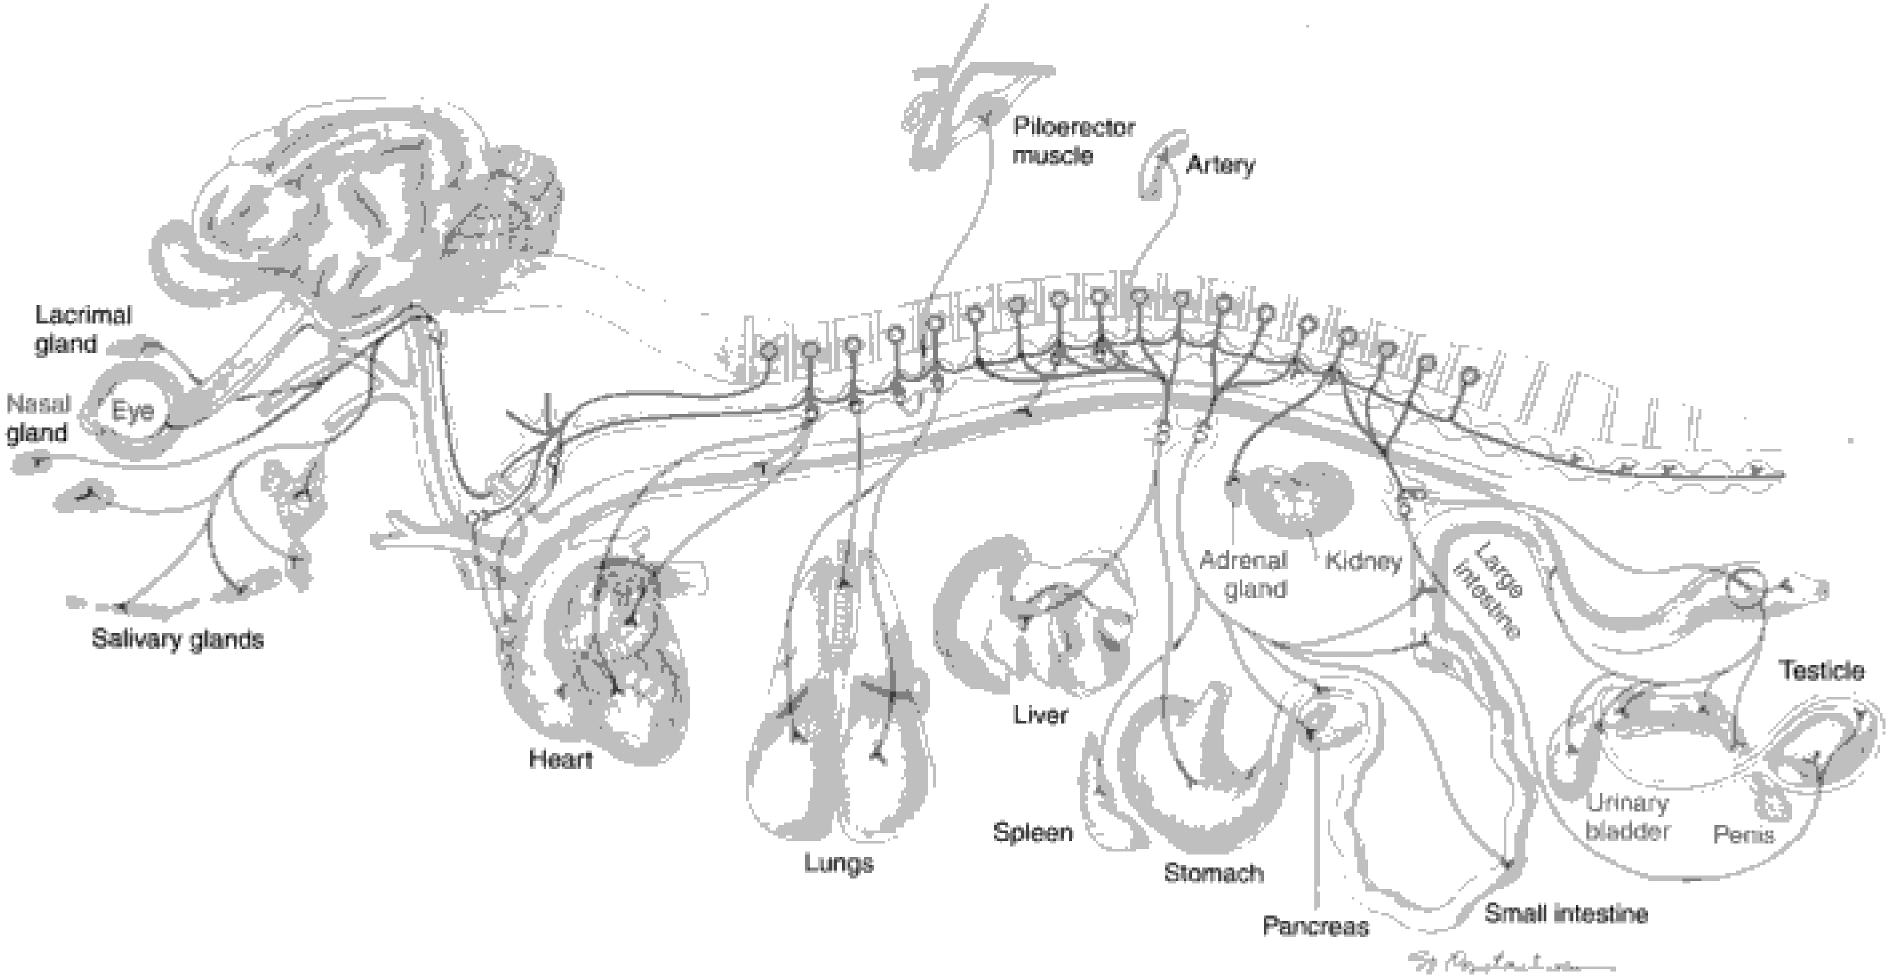

FIG. 5.1.—Anatomical representation of motor innervation from the sympathetic nervous system to various body organs and tissues. Preganglionic sympathetic neuron bodies within the thoracolumbar region of the spinal cord send axons peripherally to synapse with ganglionic neuron bodies comprising the sympathetic ganglionic chains located along each side of the vertebral column. Postganglionic axons exit the sympathetic ganglionic chains and pass peripherally to innervate those cells regulated by the sympathetic (thoracolumbar) division of the autonomic nervous system. Preganglionic fibers are red; postganglionic fibers are blue. Drawn by Dr. Gheorghe M. Constantinescu, University of Missouri. (*See also color plates following p. 118.*)

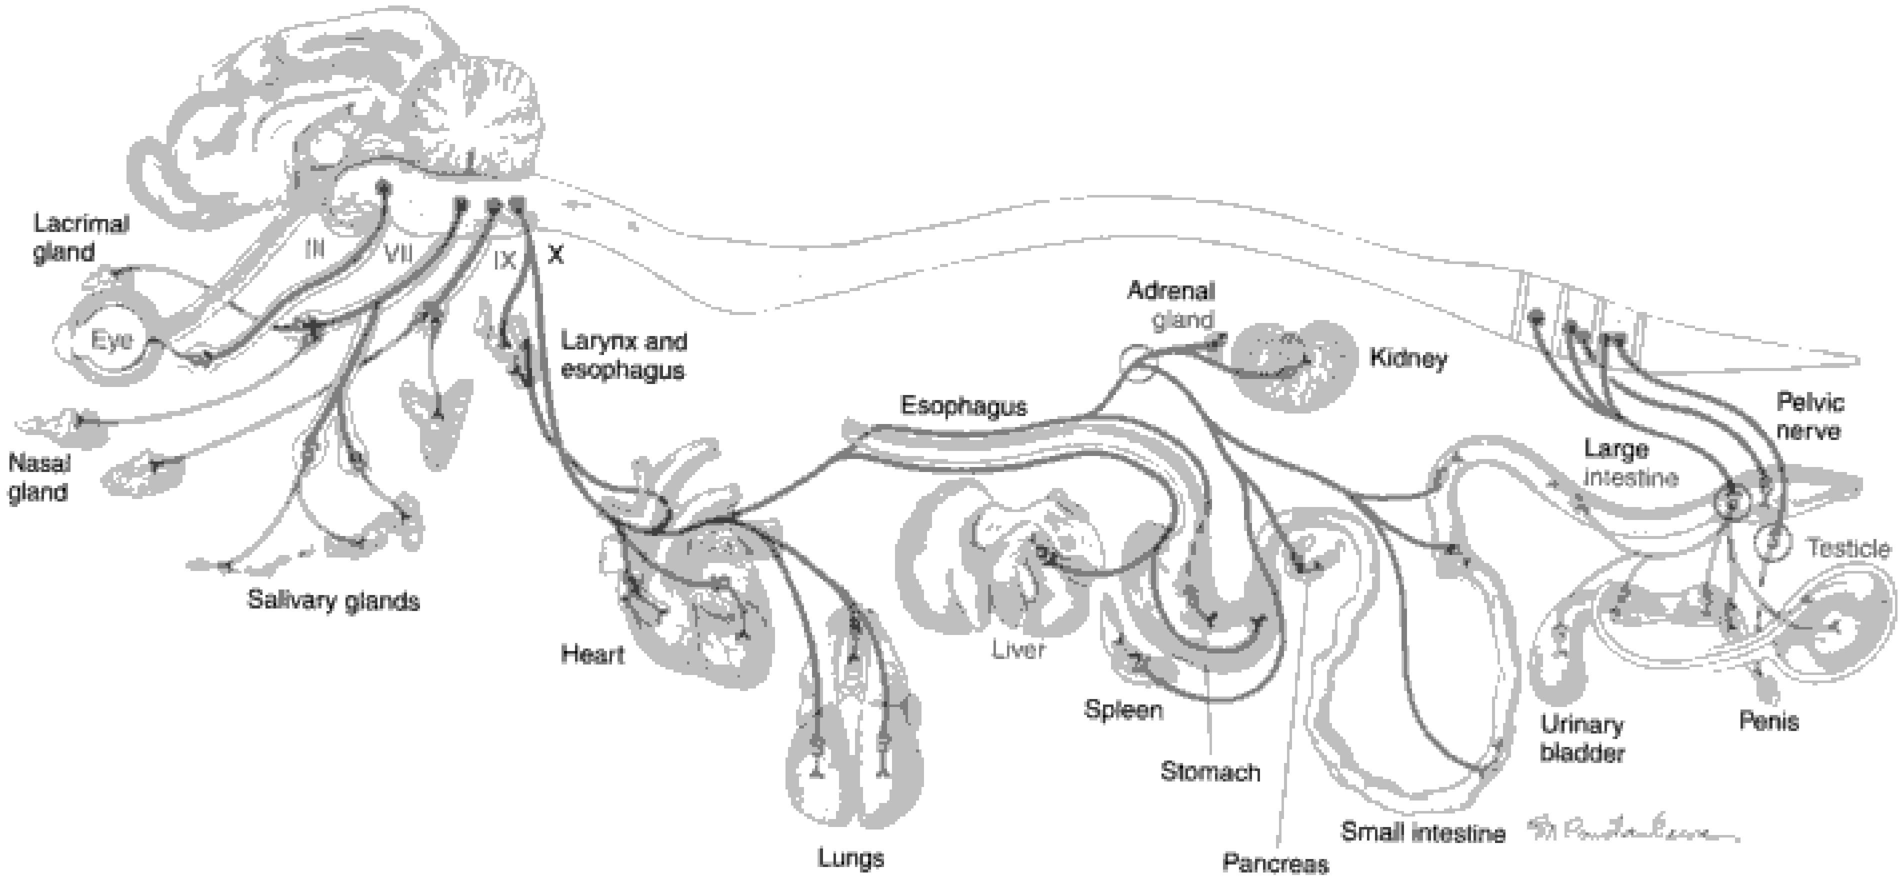

FIG. 5.2.—Anatomical representation of motor innervation from the parasympathetic nervous system to various body organs and tissues. Preganglionic parasympathetic neuron bodies within cranial and sacral zones of the central nervous system send axons peripherally to synapse with ganglionic neuron bodies localized within or adjacent to visceral tissues. Postganglionic axons exit parasympathetic ganglia and innervate those cells regulated by the parasympathetic (craniosacral) division of the autonomic nervous system. Roman numerals depict cranial nerves carrying parasympathetic neurons. Preganglionic fibers are red; postganglionic fibers are blue. Drawn by Dr. Gheorghe M. Constantinescu, University of Missouri. (*See also color plates following p. 118.*)

TABLE 5.1—Typical responses of effector tissues to sympathetic and parasympathetic nerve impulses

Effector tissues	Sympathetic-mediated responses[1]	Parasympathetic-mediated responses[2]
Heart	General excitation	General inhibition
Sinoatrial (SA) node	β_1—increase heart rate	Decrease heart rate
Atria	β_1—increase contractile force, conduction velocity	Decrease contractile force
Atrioventricular (AV) node	β_1—increase automaticity, conduction velocity	Decrease conduction velocity; AV block
His-Purkinje system	β_1—increase automaticity, conduction velocity	. . .
Ventricles	β_1—increase contractile force, conduction velocity, irritability[3]	Decrease contractile force[4]
Blood vessels		
Coronary	α_1—constriction; β_2—dilation[5]	Dilation[6]; constriction[6]
Cutaneous, mucosal	α_1—constriction	Dilation[7]
Cerebral	α_1—constriction; β—dilation	Dilation[7]
Skeletal muscle	α_1—constriction; β_2—dilation[8]	Dilation[7]
Splanchnic	α_1—constriction; β_2—dilation[9]	Dilation[7]
Renal	α_1—constriction; β_2—dilation[9]	Dilation[7]
Genital	α_1—constriction	Dilation[10]
Veins	α_1—constriction	
Endothelium	α_2—dilation	
GI tract	General inhibition	General excitation
Smooth muscle	β_2—relaxation; α—relaxation[11]	Increase motility and tone
Sphincters	α—contraction	Relaxation
Secretions	Decrease (usually)	Increase
Gallbladder and ducts	Relaxation	Contraction
Bronchioles		
Smooth muscle	β_2—relaxation	Contraction
Glands	Inhibition (?)	Stimulation
Eye		
Radial muscle, iris	α_1—contraction (mydriasis)	. . .
Sphincter muscle, iris	. . .	Contraction (miosis)
Ciliary muscle	β—relaxation; far vision	Contraction; near vision
Urinary bladder	Urinary retention	Urination
Fundus	β_2—relaxation	Contraction
Trigone, sphincter	α—contraction	Relaxation

continued

ganglia are within innervated organs. Accordingly, postganglionic parasympathetic fibers are usually quite short. Parasympathetic discharge usually is discrete and affects specific effector systems individually.

GENERAL CONCEPTS OF AUTONOMIC FUNCTION

Autonomic Interrelationships. Most visceral organs are innervated by both parasympathetic and sympathetic divisions (Figs. 5.1 and 5.2), often producing contrasting effects on the same structure. For example, parasympathetic fibers of the vagus nerve elicit a decrease in heart rate, whereas sympathetic cardiac nerves accelerate heart rate. Such reciprocating relationships allow varying degrees of qualitative, as well as quantitative, changes in organ function, depending upon the relative needs of the organism (Stuesse et al. 1979; Low 1993). Principal organ responses mediated by sympathetic and parasympathetic discharge are summarized in Table 5.1.

Another important aspect involves the unmasking of parasympathetic or sympathetic activity when the opposing system is blocked. For example, gastrointestinal (GI) functions are normally under parasympathetic dominance. Enhanced activity of this division elicits a pronounced increase in GI secretion and smooth muscle motility. However, sympathetic nerve traffic causes an inhibition of smooth muscle activity and secretory processes in the GI tract. Abolishment of parasympathetic control produces a quiescent, hypoactive GI tract characterized by sympathetic dominance. Blockage of sympathetic control to the GI tract accentuates parasympathetic activity. Such relationships are important to clinical pharmacology and explain why the response of an individual to a specific autonomic drug may present as a complex change in sympathetic and parasympathetic activity (Freeman and Miyawaki 1993).

Organ Responses to Autonomic Discharge. The sympathetic outflow tract and closely associated adrenal medulla are often referred to as the sympathoadrenal (or sympathoadrenomedullary) axis. This axis is extremely reactive. Activity varies discretely on a moment-to-moment basis consistent with the needs of the organism. Thus small changes required for homeostasis are readily accomplished. The sympathoadrenal axis can also discharge in a mass action affecting virtually all sympathetically innervated structures. Such a

TABLE 5.1—*continued*

Effector tissues	Sympathetic-mediated responses[1]	Parasympathetic-mediated responses[2]
Splenic capsule	α—contraction, β_2—relaxation	. . .
Sweat glands	Secretion (cholinergic);[12] β_2—secretion (horse)	
Salivary glands	α_1—scant, viscous secretion	Profuse, watery secretion
Piloerector muscles	α—contraction	. . .
Kidney renin release	α_2—decrease; β_1—increase	. . .
Uterus[13]	α_1—contraction; β—relaxation (nonpregnant > pregnant)	Contraction[14]
Genitalia		
Male	α—ejaculation	Erection[15]
Female	. . .	Erection[15]
Adrenal medulla	Secretion of epinephrine > norepinephrine (cholinergic)	. . .
Autonomic ganglia	Ganglionic discharge (cholinergic)	Ganglionic discharge[16]
Liver	β_2—glycogenolysis and gluconeogenesis (α in some species)	. . .
Pancreas		
Islet cells	α_2—decrease secretion; β_2—increase secretion	. . .
Acini	α—decrease secretion	Increase secretions
Fat cells	β_1—lipolysis	. . .
Adrenergic nerve terminals	α_2—decrease release of norepinephrine β_2—increase release of norepinephrine	± Release of norepinephrine[17]
Platelets	α_2—aggregation	. . .

Note: Superscript numbers are defined as follows: (1) α and β designate the principal adrenoceptor type subserving a tissue response. α_1, α_2, β_1 and β_2 designate the receptor subtype. The usual receptor types are presented; considerable interspecies variation exists, particularly with reference to subtypes. (2) Except when otherwise designated (e.g., ganglia), parasympathetic responses are subserved by muscarinic receptors. (3) Catecholamine-induced irritability of the myocardium may be associated with β_1 and α receptors; systemic pressor response may contribute. (4) Muscarinic receptors subserving decreased contractility are demonstrable in ventricular muscle, but the significance is not definitely known. (5) In small coronary arteries, β receptors are more numerous, more sensitive, and/or more responsive than α receptors. In large coronary arteries α receptors can be demonstrated. β_1 and β_2 subtypes differ depending upon species. (6) Depending upon experimental conditions, cholinergic effects on coronary blood vessels have been reported as both constriction and dilation (Kalsner 1989). (7) Arterial smooth muscle generally is not innervated by the parasympathetic nervous system (exceptions include blood vessels of genitalia). Thus cholinergic receptors in most arterial beds are not associated with parasympathetic nerves. In certain regions (e.g., arteries of skeletal muscles) sympathetic cholinergic vasodilator fibers are present, but their physiologic importance is poorly understood. (8) In skeletal muscle arteries β receptors are more sensitive than α receptors. (9) β receptors of visceral blood vessels seem less important than α receptors. (10) Parasympathetic-induced dilation of genital blood vessels (which contributes to erection) is not mediated by ACh; the neurotransmitter is believed to be nitric oxide; see (15) below. (11) β-inhibitory receptors may be localized on smooth muscle cells, whereas α-inhibitory receptors may be localized on parasympathetic cholinergic (excitatory) ganglionic cells of Auerbach's plexus. (12) In humans, sweat glands are innervated by postganglionic sympathetic axons that release ACh (i.e., cholinergic) rather than norepinephrine (i.e., adrenergic). In domestic animals, however, sweat glands are regulated by adrenergic (e.g., horse) or cholinergic mechanisms, depending upon species and type of gland (Robertshaw 1980). (13) Uterine responses vary depending on species and stage of estrus, pregnancy, and menstrual cycle (when present). (14) Contractile responses dominate; cholinergic drugs can induce severe myometrial contractions and abortion. (15) Smooth muscle erectile tissue is relaxed by parasympathetic impulses, thereby leading to vascular space engorgement and erection. The neurotransmitter at these sites is not ACh but is believed to be nitric oxide. (16) Ganglionic transmission is subserved predominantly by nicotinic receptors. (17) See Chap. 6 for distribution of α_1 and α_2 receptor subtypes in arteries. In many blood vessels endothelial α_2 receptors mediate vasodilation through the release of endothelium-derived nitric oxide. In contrast, α_2 receptors of vascular smooth muscle subserve vasoconstriction.

unitary sympathoadrenal discharge occurs in response to severe rage or fear and readies the organism for "fight or flight." Accordingly, cardiovascular activity is accelerated; an increase in heart rate, myocardial contractile strength, cardiac output, and blood pressure is observed. Blood is redistributed from splanchnic and cutaneous beds to voluntary skeletal muscles; bronchioles dilate and respiration increases; pupils enlarge; and blood glucose concentration increases. The organism is now better prepared to effectively react to the stimulus that instigated the sympathetically mediated fight-or-flight reaction.

Conversely, the parasympathetic nervous system functions mainly to regulate localized organ changes and is not organized for mass action. Whereas sympathetic activation results in expenditure of energy, the parasympathetic system reacts to generate and maintain biologic energy. Parasympathetic activity therefore has been referred to as a "live-and-let-live" type of response (Adams 1977). Digestive breakdown of nutrients, e.g., is enhanced by increased parasympathetic activity to the GI system. Myocardial oxygen consumption and energy utilization are decreased by vagal-mediated decreases in heart rate and contractile strength of the heart.

How an individual organ will respond to sympathetic or parasympathetic impulse traffic can be predicted by considering whether a particular physiologic activity would benefit the fight-or-flight response (sympathetic) or the live-and-let-live response (parasympathetic). This physiologic concept is important to the pharmacology student, because an understanding of how tissues respond to autonomic nervous activity often can be extrapolated to understanding how tissues will respond to autonomic drugs. This can save much memorization work; e.g., it is logical that an increase in heart rate, myocardial contractile strength, and cardiac output would be beneficial to an effective fight-or-flight reaction to rage or fear. Conversely, cardiac rest would be consistent with the sedentary condition of the live-and-let-live state. Thus activation of the heart would be a result of sympathetic discharge, whereas diminished cardiac activity would be a result of parasympathetic discharge. Accordingly, a sympathomimetic drug would increase cardiac function, and a parasympathomimetic drug would reduce cardiac function.

Digestion of food obviously would not be required for an immediate sympathetic reaction to stressful environmental changes. Thus sympathetic nervous system activity inhibits GI function, whereas parasympathetic (live-and-let-live) discharge increases GI function. Accordingly, a sympathomimetic drug reduces GI activity, and a parasympathomimetic drug enhances GI activity.

One apparently contradictory aspect of sympathetic-parasympathetic control is quite familiar to veterinarians. Occasionally, some animals (especially dogs and nonhuman primates) that experience profound fright will exhibit signs of increased intestinal and urinary bladder activity (i.e., defecation and micturition). However, it should be appreciated that in severe incidences of fear it is likely that parasympathetic centers in the brain will be activated by overspill of central sympathetic impulses that originate from emotional centers. Thus sympathetic inhibition of intestinal and urinary bladder activity may momentarily be overridden by parasympathetic discharge.

Information Transmission. Information is communicated from nerve to nerve and from nerve to effector organ by a process termed "neurohumoral transmission." This process involves release from a nerve terminal of a chemical neurotransmitter that reacts with specialized receptor areas on the innervated cell. Activation of the receptor instigates characteristic physiologic responses in the effector cell.

The neurotransmitter at all ganglia (both parasympathetic and sympathetic) and at most parasympathetic neuroeffector junctions is acetylcholine (ACh). In a few regions (e.g., erectile tissue of genitalia) the neurotransmitter at parasympathetic neuroeffector junctions is not ACh (Klinge and Sjöstrand 1974; Klinge et al. 1978). Norepinephrine (noradrenalin) is the transmitter released at the majority of sympathetic neuroeffector junctions and is considered to be "the" sympathetic neurotransmitter. At a few sympathetic neuroeffector junctions (e.g., sweat glands in humans) ACh is the transmitter.

Nerves that release ACh are classified chemically as cholinergic nerves. Nerves that release norepinephrine are classified chemically as adrenergic or noradrenergic nerves. A third type of nerve is classified as nonadrenergic-noncholinergic (NANC) since these neurons release neither norepinephrine nor ACh. Instead, these NANC neurons release nitric oxide as their neurotransmitter substance (Lowenstein et al. 1994). It now seems clear, e.g., that nitric oxide is the NANC neurotransmitter responsible for penile erection (see the section on nitric oxide later in this chapter).

Preganglionic and postganglionic relationships of sympathetic and parasympathetic efferent fibers are shown schematically in Fig. 5.3, which should be studied thoroughly. Often, difficulty is encountered in correlating classifications of sympathetic and parasympathetic nerves with chemical classifications of adrenergic and cholinergic nerves. An adrenergic nerve releases norepinephrine and is a sympathetic postganglionic nerve. A cholinergic nerve releases ACh but can be a parasympathetic preganglionic nerve; a parasympathetic postganglionic nerve; a sympathetic preganglionic nerve; and, in a few regions, a sympathetic postganglionic nerve. The proposed relationships for NANC nerves, which release nitric oxide, are also included in Fig. 5.3 (Änggard 1994; Adams 1996).

Central Integration of Autonomic Activity. Attention is usually directed toward the efferent adrenergic and cholinergic pathways of the autonomic nervous system. However, afferent fibers and brain nuclei that influence peripheral motor function are equally important when physiologic interactions of the autonomic nervous system are considered. Afferent fibers transmit information concerning visceral pain, cardiovascular activity, respiration, and numerous other organ functions from peripheral receptive areas to the CNS (Lang and Szilagyi 1991).

Afferent fibers are usually nonmyelinated and pass into the CNS along autonomic nerve trunks such as the vagus, pelvic, and splanchnic nerves. Sensory fibers often make up a considerable portion of autonomic nerve trunks. Nerve bodies of sensory afferent fibers are believed to be located in the dorsal root ganglia of spinal nerves and in specialized sensory ganglia of autonomic nerve trunks.

An autonomic reflex arch involves passage of information along an afferent pathway, reaction of CNS sites to the received impulse, and resulting change in efferent discharge. Well-known examples involve the baroreceptor (pressure- or stretch-sensitive) areas localized in the aortic arch and carotid sinus and the chemoreceptive cells localized in the aortic arch and carotid bodies. Information concerning blood pressure, blood O_2 and CO_2, and respiration is relayed from these sites via afferent fibers to CNS areas.

The hypothalamus is the principal supraspinal site involved in modulation of both sympathetic and

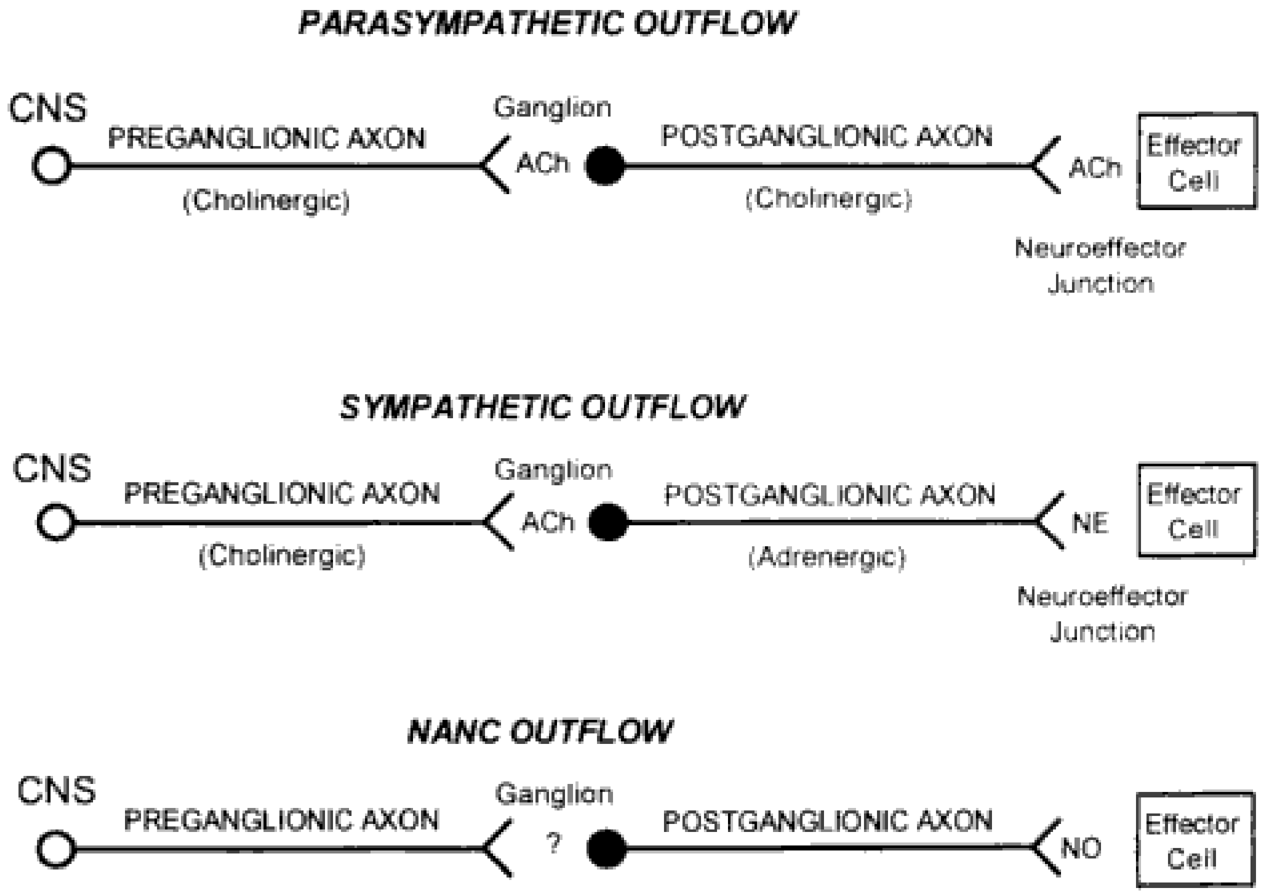

FIG. 5.3—Schematic representation of the preganglionic and postganglionic relationships of sympathetic and parasympathetic outflow tracts. ○ = CNS preganglionic nerve bodies; ● = ganglionic cell bodies. ACh is the neurotransmitter released at sympathetic and parasympathetic ganglia and at most parasympathetic neuroeffector junctions. Norepinephrine (NE) is the neurotransmitter released at adrenergic sympathetic neuroeffector junctions. (See text for exceptions.) Cholinergic fibers release ACh. Adrenergic fibers release NE. Some autonomic nerves are classified as nonadrenergic-noncholinergic (NANC) neurons; they release nitric oxide (NO), which diffuses into effector cells without the necessity of cell surface receptors. Pre- and postganglionic relationships for NANC nerves are putative. ? = the ganglionic transmitter serving NANC neurons is believed to be ACh.

parasympathetic outflow traffic. Autonomic participation in regulation of blood pressure, body temperature, carbohydrate metabolism, water-electrolyte balance, sexual responses, emotions, and sleep is mediated through hypothalamic pathways. The medulla oblongata contains nuclei that integrate blood pressure and respiration, often interacting with hypothalamic regions.

Cerebral cortical foci may also influence autonomic activity. The Pavlovian experiments are classic examples of conscious and emotional brain centers affecting peripheral autonomic activity. In these experiments, a dog was repeatedly fed only after the ringing of a bell. Eventually, ringing a bell would evoke an increase in secretory activity of the GI tract in anticipation of a meal. Such basic experiments led numerous research workers to subsequently propose that certain disorders of body viscera may actually represent psychic influence on central autonomic sites rather than organic disease.

The pharmacologic activity of certain drugs is characterized by dominant CNS effects rather than peripheral-mediated responses. Amphetamine, e.g., affects peripheral adrenergic neuroeffector junctions; however, the overall response to amphetamine in an intact animal is characterized by CNS stimulation. Conversely, some drugs used for their CNS effects (tranquilizers) may also have profound peripheral autonomic actions. The phenothiazine tranquilizers, e.g., may depress blood pressure rather markedly by blocking the interaction of norepinephrine with adrenergic receptor sites in blood vessels (Popovic et al. 1972). Such peripheral and central interactions should always be kept in mind when the total pharmacologic profile of a drug is evaluated prior to its clinical use.

NEUROHUMORAL TRANSMISSION. Most autonomic drugs used clinically exert primary pharmacologic activities by altering some essential step in the neurohumoral transmission process. In the remaining portions of this chapter, the physiologic steps involved in neurohumoral transmission will be summarized. In subsequent chapters, autonomic drugs that affect the neurohumoral transmission process in the parasympathetic and sympathetic nervous systems will be examined.

General Concepts. Discovery and subsequent characterization of events involved in communication of information from nerve to nerve and from nerve to effector organ represent major scientific achievements. Although numerous investigators have provided various relevant information, the first definitive evidence of chemical neurotransmission seems to have been obtained by Loewi (1921) and coworkers. In these simple but scientifically elegant experiments, Loewi electrically stimulated the vagus nerve of an isolated perfused frog heart. The perfusate leaving this preparation was perfused through another frog heart. Upon stimulation of the vagus nerve to the first heart, Loewi observed that this heart was immediately depressed. Within a few seconds, the second heart was also depressed. Certainly, the most logical explanation for this finding was that stimulation of the vagus nerve liberated a chemical "myocardial inhibitory" substance that was carried in the perfusate to the second heart. This substance, referred to as *Vagusstoff* (vagus substance), was later identified as ACh.

The basic techniques proved by Loewi have been modified and utilized by numerous investigators to map other adrenergic and cholinergic pathways. ACh was found to be the chemical released from all (parasympathetic and sympathetic) autonomic preganglionic fibers and most postganglionic parasympathetic fibers. Norepinephrine is the neurotransmitter released at the majority of sympathetic neuroeffector junctions (Fig. 5.3). Nitric oxide is the neurotransmitter discharged by certain NANC neurons innervating regions of the GI tract, the vasculature, and the external genitalia (Änggard 1994; Lowenstein et al. 1994).

Several criteria should be met before a chemical can be accepted as a neurotransmitter: (1) stimulation of a nerve should markedly increase the concentration of the active substance in the effluent, (2) the proposed mediator should be chemically and pharmacologically identified and characterized, (3) exogenous administration of the chemical should identically simulate nerve stimulation, (4) other drugs should have basically similar effects on responses to nerve stimulation and the proposed transmitter substance, and (5) cellular mechanisms capable of manufacturing, storing in an inactive form, and inactivating the neurotransmitter should be demonstrable (Lefkowitz et al. 1990).

Physiologic Events. Events involved in neurohumoral transmission at neuroeffector junctions can be subdivided into axonal conduction, synthesis and release of the neurotransmitter, receptor events, and catabolism of the neurotransmitter.

AXONAL CONDUCTION. Axonal conduction refers to the passage of an impulse along a nerve fiber. It is dependent upon selective changes in the permeability of the axonal membrane to electrolytes. At rest, membrane potential within mammalian axons is approximately −85 mV. This negative intracellular potential is maintained at rest basically because the axonal membrane is relatively more permeable to K^+ than to Na^+. Na^+ ions are in higher concentration in extracellular than in intracellular fluid, whereas K^+ ions are in greater concentration in intracellular than in extracellular fluid. The relatively small amounts of K^+ that leak into the interstitial space in conjunction with the large number of organic anions that are intracellular result in a net negative charge within the axon.

An action potential reflects a reversal of the polarization state present at rest and is the result of permeability changes that occur at the axonal surface as an impulse is propagated along a nerve fiber. A suprathreshold stimulus initiates a localized change in the permeability of the axonal membrane. Suddenly, permeability of the fiber to Na^+ is greatly increased in relation to K^+; Na^+ moves inward in the direction of its large electrochemical gradient. This movement is detected by an instantaneous change in the membrane potential in a positive direction. The positively charged Na^+ increases in concentration within the axon; the membrane potential moves from −85 mV toward zero and then overshoots to the extent that momentarily the inside of the fiber is positive in relation to the exterior of the cell.

Repolarization of the membrane occurs rapidly as the selective permeability characteristics of the axonal membrane are quickly reestablished. The axon once again becomes relatively impermeable to Na^+ and relatively more permeable to K^+, and the negativity of the interior of the cell is quickly reestablished. A schematic representation of axonal conductance and resulting neurohumoral transmission events is presented in Fig. 5.4.

Although the localized permeability changes associated with an action potential are extremely short-lived, they elicit similar alterations in membrane function in immediately adjacent quiescent areas of the axon. Thus the action potential is self-propagating, and in this manner an action potential is conducted along an axonal fiber. Over long periods the absolute concentration gradients of electrolytes are maintained by energy-utilizing transport systems such as the sodium pump. The axonal membrane is refractory for a brief interval after the passage of an action potential, thereby preventing antidromic and excess impulse traffic.

Axonal conduction is insensitive to most drugs. Even local anesthetics must be used in high concentrations in immediate contact with the nerve before excitability is blocked. However, subsequent events in neurohumoral transmission are quite susceptible to drug actions.

NEUROTRANSMITTER RELEASE. Release of neurotransmitter substance is triggered by arrival of the axonal action potential at the nerve terminal (Fig. 5.4) (Klein 1973; Winkler and Hörtnagl 1973). Ca^{++} acts to link or couple the excitation of the membrane (action potential) with discharge of neurotransmitter from the axon terminal. The action potential initiates an inward movement of Ca^{++} into the nerve terminal from the interstitial space and/or superficial membrane binding sites at the axon terminal. Inward movement of Ca^{++}

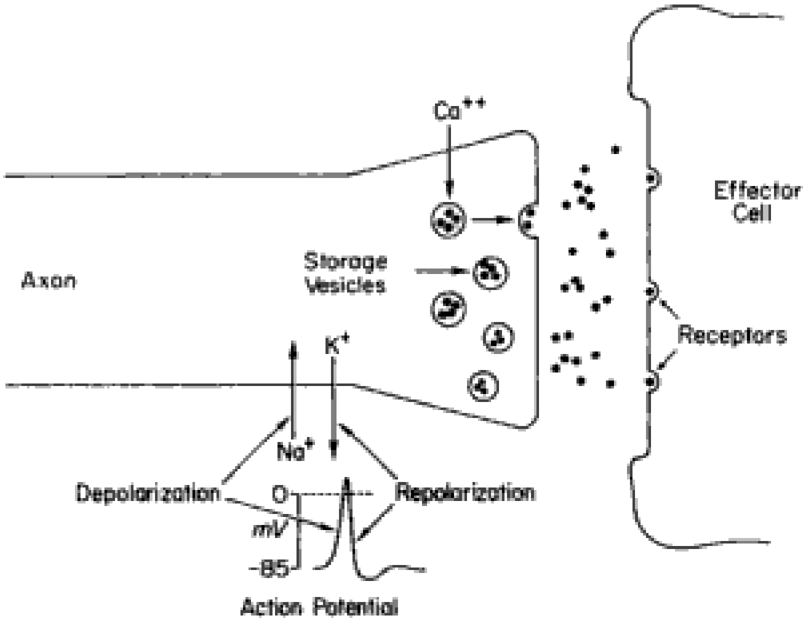

FIG. 5.4—Schematic representation of neurohumoral transmission. The axonal action potential represents a self-propagating depolarization-repolarization of the axon that is characterized by an influx of Na^{+} and an efflux of K^{+}. As the action potential arrives at the nerve terminal, it facilitates an inward movement of Ca^{++}, which triggers the discharge of neurotransmitter (●) from storage vesicles into the junctional cleft. Neurotransmitter reacts with specialized receptor areas on the postjunctional membrane and initiates a physiologic response in the effector cell.

triggers exocytotic discharge of neurotransmitter from the vesicles into the junctional cleft (Rubin 1982). Nitric oxide is not stored in synaptic vesicles. Instead, the increase in cytosolic Ca^{++} activates a Ca^{++}-dependent enzyme: nitric oxide synthase. The activated form of this enzyme utilizes molecular oxygen and a nitrogen moiety from the amino acid L-arginine to yield nitric oxide. The latter is highly lipophilic and it rapidly diffuses to effector cells (Adams 1996).

RECEPTOR EVENTS. After rapid migration of neurotransmitter across the cleft, the mediator substance bonds with receptive areas on the postsynaptic membrane. Cell surface receptors are specialized macromolecular structures of the cell that a neurotransmitter interacts with to elicit a response (Abramson and Molinoff 1984). Many types and subtypes of receptors have now been isolated and cloned. The clinical utility of all such discoveries remains to be defined.

Receptor events caused by interaction of neurotransmitter substance with the receptor may be of two general types: excitatory or inhibitory. If the neurotransmitter initiates an excitatory response in the cell, receptor activation triggers a general increase in permeability of the postsynaptic membrane to all ions. Thus, in a manner analogous to the axonal action potential, there is a sudden depolarization-repolarization of the postsynaptic membrane characterized by a net inward movement of Na^{+} and an efflux of K^{+} along their respective concentration gradients. Electrically, these changes are characterized as an excitatory postsynaptic potential, which then propagates localized permeability changes in adjacent portions of the cell membrane, and an action potential is conducted along the remainder of the innervated cell.

An inhibitory postsynaptic potential occurs when the neurotransmitter initiates a selective increase in permeability of the postsynaptic membrane to only smaller ions (e.g., K^{+}, Cl^{-}). Thus outward movement of K^{+} and inward movement of Cl^{-} along their respective concentration gradients increase the net negative charge within the cell and actually hyperpolarize the postsynaptic membrane. The resulting hyperpolarization of the membrane increases the threshold to stimuli and, in effect, elicits an inhibitory response in the cell.

CATABOLISM OF NEUROTRANSMITTER. Termination of the duration of action of released neurotransmitter substances involves different mechanisms. The adrenergic neurotransmitter norepinephrine is metabolized by both intraneuronal and extraneuronal enzymes. However, the uptake of norepinephrine back into the adrenergic nerve terminal and diffusion of norepinephrine away from receptor sites are probably more important pathways for termination of norepinephrine activity. Extraneuronal ACh is rapidly hydrolyzed by acetylcholinesterase (AChE), a quite specific enzyme localized in close proximity to the synaptic cleft. Nitric oxide is a highly reactive free radical, and it undergoes oxidation to nitrites and nitrates within seconds.

ADRENERGIC NEUROHUMORAL TRANSMISSION. For critical examination of adrenergic mecha-

nisms, the interested reader is referred to the detailed bibliography accumulated by Lefkowitz et al. (1990).

Catecholamines. Norepinephrine, epinephrine, and dopamine are endogenous catecholamines; they are the sympathetic neural and humoral transmitter substances in most mammalian species. Norepinephrine and dopamine are believed to transmit impulse information in specific areas within the CNS; norepinephrine is also the neurotransmitter at most peripheral sympathetic neuroeffector junctions. Epinephrine is the major hormone released from the adrenal medulla. Catecholamines are stored in an inactive form within granular structures in nerve terminals and chromaffin cells (Hokfelt 1973).

SYNTHESIS. Norepinephrine is synthesized from the amino acid phenylalanine in a stepwise process summarized in Fig. 5.5. The aromatic ring of phenylalanine is hydroxylated by action of an enzyme, phenylalanine hydroxylase. This reaction yields tyrosine, which is converted to dihydroxyphenylalanine (dopa) by the enzyme tyrosine hydroxylase. This reaction involves additional hydroxylation of the benzene ring, and it is believed to represent the rate-limiting step in catecholamine synthesis (Vulliet et al. 1980).

Dopa is decarboxylated by the enzyme L-aromatic amino acid decarboxylase (dopa decarboxylase) to dihydroxyphenylethylamine (dopamine). Conversion of tyrosine to dopa to dopamine is believed to occur within the cytoplasm. Dopamine is taken up into the storage granule. In some central anatomic sites (e.g., mammalian extrapyramidal system), dopamine seems to act as the primary neurotransmitter rather than its metabolites, norepinephrine and epinephrine (Aghajanian and Bunney 1973; Bartholini et al. 1973).

In peripheral adrenergic neurons and adrenal medullary chromaffin cells, intragranular dopamine is hydroxylated in the β position of the aliphatic side chain by dopamine-β-hydroxylase to form norepinephrine. In the adrenal medulla, norepinephrine is released from the granules of chromaffin cells and is *N*-methylated within the cytoplasm by phenylethanolamine *N*-methyltransferase to form epinephrine. Epinephrine is subsequently localized in what seems to be another type of intracellular storage granule prior to its release from the adrenal medulla.

STORAGE, RELEASE, REUPTAKE, AND METABOLISM. Physiologic events involved in adrenergic neurotransmission and susceptibility of these events to pharmacologic agents are outlined schematically in Fig. 5.6.

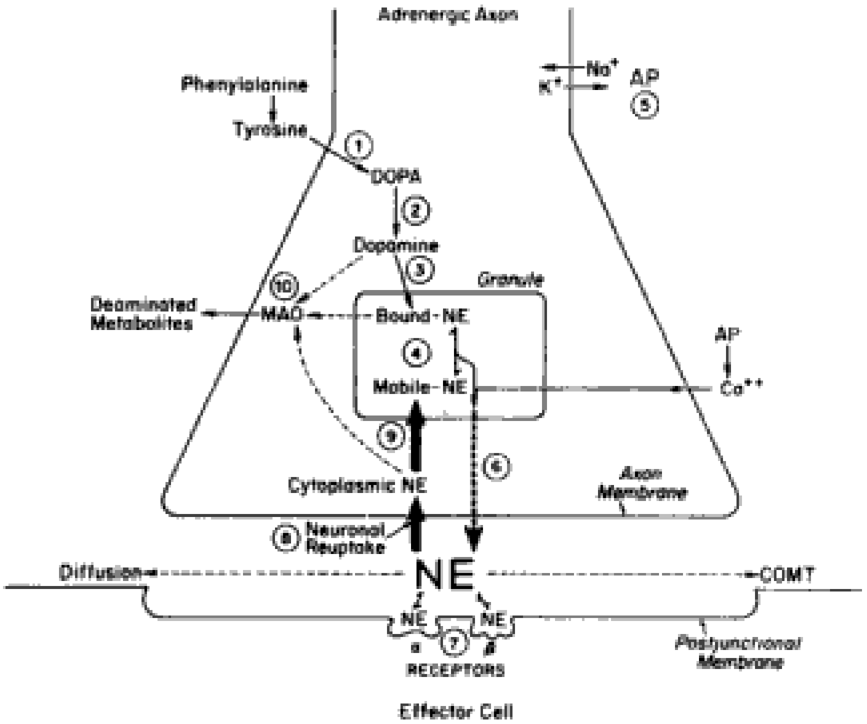

FIG. 5.6—Neurohumoral transmission at the adrenergic neuroeffector junction: proposed physiologic pathways and sites of action susceptible to modification by pharmacologic agents. (1) Tyrosine is hydroxylated to dopa. This reaction, considered to be the rate-limiting step in catecholamine synthesis, is inhibited by α-methyl-*p*-tyrosine. (2) Dopa is decarboxylated to dopamine. Dopa decarboxylase inhibitors (e.g., α-methyldopa) inhibit this step. (3) Dopamine is taken up into the storage granules and oxidized to norepinephrine (NE). α-Methyldopamine inhibits conversion of dopamine to NE and is converted to α-methylnorepinephrine. α-Methyl NE is then stored in the granule and upon nerve stimulation may be released as a "false neurotransmitter." (4) NE is stored in the granule in a bound and free (mobile) form. Tyramine-like drugs release NE from adrenergic neurons. (5) The axonal action potential is a self-propagating depolarization process that upon reaching the nerve terminal increases influx of Ca^{++}, which then triggers the discharge of NE from the nerve terminal. Bretylium inhibits NE release. (6) NE is released from the neuron via exocytotic emptying of the contents of storage granules into the junctional cleft. Newly synthesized NE may be preferentially released. (7) Released NE reacts with receptor sites on the postjunctional membrane of the effector cell. This step is blocked by adrenergic blocking agents (e.g., α-phentolamine, β-propranolol). Receptive areas (that modify NE release) may also be located on the prejunctional membrane of the nerve terminal (see Fig. 5.7). (8) Extraneuronal NE can be taken back up into the nerve terminal by an active Na^+-dependent uptake process. This step is inhibited by cocaine and imipramine-like drugs. Extraneuronal NE may also diffuse from the junction or be catabolized by catechol-O-methyltransferase. (9) Cytoplasmic NE may be taken up into the granule by a Mg^{++}-ATP-dependent uptake process. Reserpine-like drugs inhibit this step. (10) Monoamine oxidase (MAO) can deaminate cytoplasmic NE and dopamine. MAO inhibitors (e.g., pargyline) suppress this step. The bold dashed line = release of NE from the granular pool into the junctional cleft. Small dashed lines = catabolic pathways. Bold solid lines = uptake processes. Double-headed arrows = reversible pathways.

Catecholamines are taken up from the cytoplasm into granules by an active transport system that is adenosine triphosphate (ATP) and Mg^{++} dependent. Storage within the granular vesicles is accomplished by complexation of the catecholamines with ATP and a specific protein, chromogranin. This complexation renders the amines inactive until their release (Shore 1972). The intragranular pool of norepinephrine is the principal source of neurotransmitter released upon nerve stimulation. The cytoplasmic amine pool is taken up by the granules for storage or inactivated by a deaminating enzyme, monoamine oxidase (MAO), that is located in the neuronal mitochondria.

Excitation-secretion coupling and release of norepinephrine from adrenergic nerve terminals are dependent upon an inward movement of Ca^{++}. Released norepinephrine migrates across the synaptic cleft and interacts with specific adrenergic receptor sites on the postjunctional membrane.

A very active amine uptake system is present in the axonal membrane of postganglionic sympathetic nerve terminals. This transport system is Na^+ and energy dependent, and it functions to recapture or reuptake catecholamines that have been released from the nerve. Exogenously administered norepinephrine and epinephrine are taken up into sympathetic nerve endings by this uptake process (Iverson 1973). Conservation of catecholamine neurotransmitters by reuptake is one of the first examples of recycling used products.

The adrenergic neuronal uptake mechanism is referred to as $Uptake_1$. $Uptake_2$ signifies the extraneuronal uptake of catecholamines into surrounding tissue.

The duration of action of norepinephrine can be terminated by active reuptake via Uptake$_1$ into the nerve across the axoplasmic membrane (the amine reuptake pump), diffusion from the cleft via extracellular fluid, or metabolic breakdown by an extraneuronal enzyme, catechol-*O*-methyltransferase (COMT). Activity of COMT involves methylation of one of the ring hydroxyl groups (3-OH).

Norepinephrine that has been taken back into the nerve may be restored in granules or deaminated by MAO. Deamination of norepinephrine or epinephrine by MAO initially yields the corresponding aldehyde, which in turn is further oxidized to 3,4-dihydroxymandelic acid. Alternatively, the 3-hydroxyl group of norepinephrine and epinephrine can first be methylated by COMT to yield normetanephrine and metanephrine respectively. The *O*-methylated or deaminated metabolites can then be acted upon by the other enzyme to yield 3-methoxy-4-hydroxymandelic acid. The deaminated *O*-methylated metabolites can then be conjugated with sulfate or glucuronide prior to excretion by the kidneys.

PHARMACOLOGIC CONSIDERATIONS. Many drugs exert their pharmacologic activity by altering the synthesis, storage, and release mechanisms of catecholamines. Most of these agents are used in humans to control hypertension or affect central autonomic centers (e.g., tranquilization, antidepression, antiparkinsonism). Few of these drugs are commonly employed in clinical veterinary medicine. Some of these drugs are briefly mentioned, however, because they are often used as model drugs in research to characterize the mechanism of action of new drugs intended for clinical veterinary use.

Certain drugs act as false substrates for the catecholamine-synthesizing enzymes; e.g., α-methylparatyrosine inhibits tyrosine hydroxylase, the rate-limiting step in norepinephrine formation. Thus norepinephrine stores are not replenished by newly synthesized norepinephrine. Alpha-methyldopa may be converted to α-methyldopamine to α-methylnorepinephrine by dopa decarboxylase and dopamine-β-hydroxylase respectively. The α-methylnorepinephrine is active at CNS α_2 receptors, which reduce sympathetic efferent nerve traffic to the cardiovascular system.

Reserpine-like drugs block the granular uptake process (Shore 1972). Catecholamine stores are depleted and adrenergic functions are markedly altered by prolonged treatment with even small doses of reserpine (Adams et al. 1971, 1972). Guanethidine can slowly deplete norepinephrine and interfere with its release. Bretylium blocks the neuronal release of neurotransmitter. The experimental drug 6-hydroxydopamine produces a functional peripheral sympathectomy by destroying adrenergic nerve terminals (Gauthier et al. 1974).

Other drugs (e.g., cocaine, imipramine) inhibit the neuronal reuptake process so that released norepinephrine is available for a longer period for reaction with receptor sites. Inhibition of MAO by drugs can result in accumulation of catecholamines. Drugs like tyramine and amphetamine release intraneuronal stores of catecholamines.

Most adrenergic drugs important to clinical veterinary medicine act primarily by activating or blocking postjunctional adrenergic receptors in peripheral tissues or the CNS.

Adrenergic Receptors. The interaction of neurohormone with an adrenergic receptor (i.e., adrenoceptor) may elicit either an excitatory or an inhibitory response. Following isolation and identification of norepinephrine as the adrenergic neurotransmitter, attention was directed to differences in postjunctional events that might explain such contrasting results. In his classic paper, Ahlquist (1948) proposed that there were two basic types of adrenergic receptors: α and β. Epinephrine is the most potent α-receptor stimulant, norepinephrine is intermediate, and isoproterenol is the least active. On the other hand, isoproterenol is the most potent β-receptor agonist, epinephrine is intermediate, and norepinephrine is least active. Epinephrine is therefore classified as a mixed α-β agonist, whereas isoproterenol is virtually a pure β agonist with few, if any, α-receptor effects. Norepinephrine is primarily an α agonist; however, it does activate the excitatory β receptors in the heart.

Receptor Subtypes. The concept of dissimilar adrenoceptors has been strongly supported by observations that certain adrenergic antagonists block only α or β receptors (Moran 1973). Furthermore, studies with selective antagonists and agonists have demonstrated that β receptors can be divided into two subtypes: β_1 and β_2 (Lands et al. 1967). Beta receptors in the heart are β_1; they are associated with excitatory responses. Isoproterenol, epinephrine, and norepinephrine activate β_1 adrenoceptors. Beta$_2$ receptors are localized in vascular smooth muscle and bronchiolar smooth muscle; they instigate inhibitory (relaxant) effects. Norepinephrine has little effect on β_2 receptors, whereas epinephrine and isoproterenol are very active at β_2-receptor sites.

Alpha receptors located at adrenergic nerve terminals show a somewhat different responsiveness to drugs when compared to the classic α receptors of effector cells, leading to their designation as α_2 (Starke et al. 1977; Langer 1980). Other studies have supported the existence of different α-receptor populations but indicate that α_1 and α_2 subtypes are not necessarily restricted to postjunctional and prejunctional localizations respectively (U'Prichard and Snyder 1979).

Designation of adrenoceptors as either α_1, α_2, β_1, or β_2 is now well accepted. A summary of the different adrenergic receptor types in various sympathetically innervated tissues is given in Table 5.1. Numerous studies have now established that classification of receptor types and subtypes is far more complex than Ahlquist (1948) envisioned. Indeed, there may be many

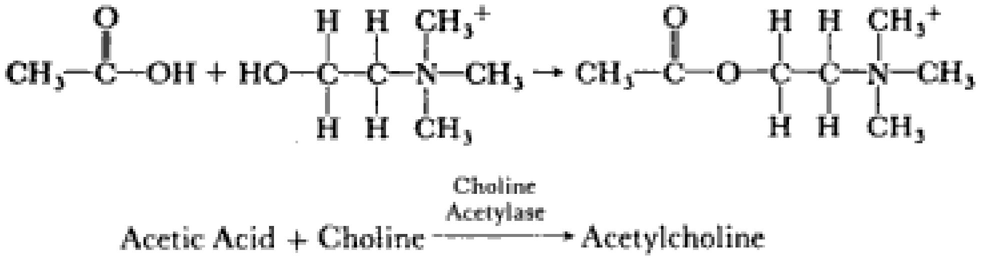

FIG. 5.7—Formation of ACh involving choline acetylase, choline, and acetic acid. Source of the acetic acid moiety is acetyl coenzyme A.

types of α receptors, β receptors, muscarinic receptors, nicotinic receptors, and others (Alberts 1993). Because the clinical importance of such complexities remains to be established, this textbook will consider clinically relevant receptor nomenclatures.

CHOLINERGIC NEUROTRANSMISSION. ACh is the neurotransmitter substance at most parasympathetic neuroeffector junctions, autonomic ganglia, the adrenal medulla, somatic myoneural junctions, and certain CNS regions (Brimblecombe 1974; Waser 1975; Goldberg and Hanin 1976). Neurohumoral transmission processes seem to be basically similar at all cholinergic junctions. Autonomic ganglionic and somatic myoneural transmission will be discussed in greater detail in subsequent chapters.

Synthesis, Storage, Release, and Catabolism of ACh. ACh is synthesized within cholinergic nerves by the enzymatic transfer of an acetyl group from acetyl coenzyme A to choline. This reaction is catalyzed by the enzyme choline acetylase (also referred to as choline acetyltransferase) and is summarized in Fig. 5.7. The acetyl coenzyme A is formed by the action of an enzyme, acetyl kinase, which mediates the transfer of an acetyl group from adenylacetate (formed from acetate and ATP) to the coenzyme A molecule. Choline is transported from the extracellular fluid into the cholinergic nerve by an energy-requiring axoplasmic uptake process. ACh is stored within axonal vesicular structures in a concentrated solution or bound to membranes or both.

ACh is released from the nerve terminal upon arrival of an axonal action potential. ACh within the junctional space is rapidly inactivated by hydrolysis by a specific enzyme, AChE. AChE is present in cholinergic nerves, autonomic ganglia, and neuromuscular and neuroeffector junctions. A somewhat similar enzyme, pseudocholinesterase (butyrocholinesterase), is present in serum and other body tissues.

Cholinergic Receptors. There are two basic types of cholinergic receptors within the peripheral efferent autonomic nerve tracts: nicotinic and muscarinic. Early studies demonstrated that small doses of nicotine mimicked certain actions of ACh, and large doses inhibited the same ACh responses. The nicotinic responsive sites were found to be present in autonomic ganglia, adrenal medullary chromaffin cells, and also the neuromuscular junction of the somatic nervous system. Accordingly, these sites have been referred to as nicotinic cholinergic receptors.

Nicotine does not, however, simulate or block the action of ACh at the parasympathetic neuroeffector junctions in heart muscle, smooth muscle, or secretory glands. The plant alkaloid muscarine was found to simulate the activity of ACh at these sites but not at the previously described nicotinic receptors. Muscarinic receptors therefore designate the type of receptor present at cholinergic neuroeffector junctions in muscle and glands.

A nicotinic response usually denotes an excitatory response, whereas muscarinic receptor activation may elicit an excitatory or inhibitory response, depending on the tissue. This seems to be related to either a general increase in permeability to all ions (depolarization-excitatory) or a selective increase in permeability to small ions like K^+ (hyperpolarization-inhibitory) respectively. Nicotinic and muscarinic cholinergic receptors have been placed into different subtypes (Birdsall et al. 1983; Chassaing et al. 1984), but the relevance of these subclassifications to clinical veterinary medicine is unclear at this time.

Pharmacologic Considerations. A wide variety of chemical and biologic agents affect cholinergic neurotransmission. The synthesis of ACh is inhibited by hemicholinium, which blocks the entrance of choline into the cholinergic nerve. Botulinum toxin interferes with the release of ACh. The plant alkaloids nicotine and muscarine have been mentioned in preceding paragraphs. Atropine and related alkaloids block muscarinic receptors, whereas curare blocks nicotinic receptor sites. The activity of endogenous and exogenous ACh is markedly augmented by many chemicals that act as cholinesterase inhibitors (anticholinesterase agents). The therapeutic importance of cholinergic and anticholinergic agents will be discussed in Chap. 7.

AUTONOMIC RECEPTOR SITES ON NERVE TERMINALS. Release of autonomic transmitters from nerve terminals can be influenced by other transmitters interacting with specific receptor sites present on the nerve terminal (for reviews, see Adams 1983, 1984).

Muscarinic cholinergic receptors at adrenergic nerve endings mediate an inhibition of the neuronal release of norepinephrine (Muscholl 1973). Such receptors may well explain the reduced cardiac responses to sympathetic nerve activity when vagal influence is increased (Stuesse et al. 1979). Several unrelated autacoids (e.g., histamine, prostaglandins) also inhibit norepinephrine release from adrenergic nerves, evidence for inhibitory presynaptic receptors specific for certain autacoids (Horton 1973; Langer 1980).

There also is evidence for α_2- and β_2- adrenoceptive sites on adrenergic nerve terminals (Starke et al. 1977; Langer 1980). Prejunctional α_2 receptors mediate a decrease in the amount of norepinephrine released upon nerve stimulation. The function of these α_2 sites has been envisioned as a local feedback control mechanism through which norepinephrine can inhibit its own release once a threshold concentration has been obtained in the junctional space. Conversely, the prejunctional β_2 receptors subserve increased release of norepinephrine (Adams 1984).

It is tempting to speculate on the physiologic significance and implications of such local inhibitory-facilitatory feedback mechanisms. However, although these extremely complex interrelationships most likely exist, neither the complete physiologic nor the complete pharmacologic significance of all presynaptic receptors has been definitely established at this time. The clinical relevance of the α_1- and α_2-receptor subtypes and β_1- and β_2-receptor subtypes is considered in Chap. 6.

PUTATIVE NEUROHUMORAL SUBSTANCES. Biologic substances other than ACh and the catecholamines have been proposed as probable (putative) neurotransmitter substances. Histamine, e.g., has been suggested as a potential neurotransmitter at certain peripheral and CNS sites, as have different neuropeptide substances. There is even evidence now that certain peptides coexist in the same neuron as primary neurotransmitters (Iverson et al. 1983). It remains unclear whether these peptides serve as primary neurotransmitters themselves or, more likely, modulate either the axon or the effector cell process in the neurohumoral communication event.

Considerable evidence has revealed that serotonin (5-hydroxytryptamine) acts as a neurotransmitter in specific brain centers and some peripheral nerves. The functional consequences of tryptaminergic transmission have not been completely defined, but it is likely that 5-hydroxytryptamine participates in thermoregulation, sleep cycles, and extrapyramidal influences on motor control of skeletal muscles. Gamma-aminobutyric acid has been shown to be an inhibitory neurotransmitter at certain CNS sites.

Although several putative neurotransmitter substances are involved in information transfer in the central and peripheral nervous systems, the pharmacologic activity of most autonomic drugs and numerous centrally acting agents can best be explained by actions on cholinergic or adrenergic pathways.

NITRIC OXIDE. Nitric oxide is an unlikely candidate for an endogenously synthesized messenger for physiologic and pathophysiologic communications in living organisms (Lowenstein et al. 1994; Adams 1996). Compared to classical neurotransmitters and polypeptides, nitric oxide is an exceptionally small and simple molecule comprising a single atom each of nitrogen and oxygen and existing under atmospheric conditions as a gas. With an unpaired electron in its outer orbit, nitric oxide is a radical species with a biological half-life of only a few seconds; it reacts rapidly with oxygen or with iron moieties of heme-containing proteins. Nitric oxide also is a combustion product generated in cigarette smoke, smog, and jet engine exhaust.

Despite considerable interest in nitric oxide as an environmental pollutant, it gathered little notice from biomedical scientists until the recent discovery that this compound is actively synthesized by different cell types, where it serves as a key regulator of a wealth of different bodily functions. These include immunomodulation, antimicrobial defenses, tumoricidal activity, neurotransmission in both the central and peripheral nervous systems, respiration, intestinal peristalsis, penile erection, and cardiovascular dynamics. The idea that a small molecule of gas can be synthesized by mammalian cells and then serve as a key controller of physiologic functions truly represents a new frontier in medicine (Adams 1996).

The surge of biomedical interest in nitric oxide can be traced directly to several lines of investigation involving the biochemistry of carcinogenesis, immunomodulatory and antimicrobial characteristics of activated macrophages, and control of hemodynamics (Änggard 1994; Langrehr et al. 1993). Relative to vascular effects, the discovery of endothelium-derived relaxing factor (EDRF) by Furchgott and Zawadzki (1980) unquestionably was a pivotal step in the recognition that mammalian cells can synthesize nitric oxide. These investigators observed that ACh produced vasodilation in isolated blood vessels only when the vascular endothelium was intact. This classical observation prompted an explosion of interest in vascular endothelium as a necessary intermediary in the vascular smooth muscle relaxation induced not only by ACh but also by many other vasodilators, including bradykinin, thrombin, oxytocin, adenosine diphosphate, and substance P. It became clear that when such agents interacted with vascular endothelium, the latter released an endogenous factor responsible for vasorelaxant responses to the former—hence, the discovery of EDRF (Furchgott and Zawadzki 1980). Depending on species and vascular bed, some vasodilator agents exert both endothelium-dependent and endothelium-independent actions as part of their pharmacodynamic profiles (Cogswell et al. 1995).

Following studies with exogenous nitrovasodilators that release nitric oxide (such as nitroglycerin and nitroprusside) and endothelium-dependent vasodilators (such as ACh and bradykinin), different investigators concluded that the pharmacodynamic and pharmacokinetic characteristics of EDRF closely mimicked those of nitric oxide. It is now widely accepted that EDRF is in fact either authentic nitric oxide, a closely related nitrosothiol that releases nitric oxide to target cells, or both. Nitric oxide migrates from the endothelium and activates the cytosolic form of guanylyl cyclase in adjacent vascular smooth muscle cells. This activation accelerates conversion of guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP), with the latter leading in turn to relaxation of vascular smooth muscle and its accompanying vasodilation.

Endothelium-derived nitric oxide was not simply an experimental curiosity of isolated blood vessels. Indeed, pharmacologic inhibition of nitric oxide biosynthesis in intact animals elicits a pronounced systemic hypertensive response owing to a substantial increase in peripheral vascular resistance. Because this peripheral vasoconstriction is expressed under basal conditions, it became clear that EDRF is an important modulator of normal vasodilator tone regulated by a dynamic release of endothelium-derived nitric oxide on a moment-to-moment basis. These remarkable findings revolutionized long-held concepts about control of peripheral vasomotion, prompting robust searches for different agents that would selectively modulate the biosynthesis of nitric oxide.

Nitric Oxide Biosynthesis. Details of the complex biochemical and electron-transfer steps culminating in the formation of nitric oxide have been reviewed (Änggard 1994; Langrehr et al. 1993; Lowenstein et al. 1994; Schulz and Triggle 1994). In brief, nitric oxide is synthesized from an N^G-guanidino nitrogen of the amino acid L–arginine. The D–enantiomer of arginine is inactive. The enzyme family responsible for nitric oxide biosynthesis is nitric oxide synthase (NOS). Because this enzyme family utilizes molecular oxygen, NOS is classified as a dioxygenase. Cofactors required for nitric oxide formation include flavin adenine dinucleotide, flavin mononucleotide, nicotinamide adenine dinucleotide phosphate (NADPH), heme, and tetrahydrobiopterin. In addition to nitric oxide, the amino acid citrulline is a coproduct in a 1:1 stoichiometric relationship with nitric oxide. The production of tritiated citrulline from tritiated L–arginine is commonly used as an indirect assay for NOS activity and nitric oxide synthesis.

Several different isoforms of NOS have been characterized, and the identifying nomenclatures are still undergoing modification as new molecular and cofactor requirements are discovered. The two original isoforms described were the constitutive NOS (cNOS) and the inducible NOS (iNOS).

The NOS prototypically present in endothelium and neurons is cNOS; this enzyme is constitutively present under basal conditions, and its activation is dependent upon calmodulin and Ca^{++}. Nitric oxide synthesis from cNOS is activated within seconds to minutes after intracellular Ca^{++} is increased in response to classical cell surface receptors and affiliated signal-transduction mechanisms that culminate in elevated cytosolic Ca^{++}. The cNOS synthesizes nitric oxide in relatively small amounts; synthesis dynamically ceases as cellular Ca^{++} falls to basal concentrations. The biosynthesis of endothelium-derived nitric oxide and its subsequent role as an activator of guanylyl cyclase in vascular smooth muscle are schematized in Fig. 5.8.

The iNOS is prototypically induced in macrophages and hepatocytes, but it is not present in these or other cell types under basal conditions. When macrophages are exposed to LPS and/or certain cytokines such as tumor necrosis factor-α or interleukin-1, de novo synthesis of nascent iNOS is initiated by transcriptional regulation. Several hours are required for maximal expression of iNOS, which produces amounts of nitric oxide large enough to destroy pathogenic microorganisms. Although calmodulin is an integral subunit component of iNOS, its regulatory role is unknown in that Ca^{++} does not seem to be required for iNOS activity.

Recent experiments have provided evidence that iNOS is not restricted to macrophages and hepatocytes; it can also be induced in a rather impressive spectrum of different cell types including vascular smooth muscle, endothelium, Kupffer cells, neutrophils, and possibly cardiac myocytes (Schulz and Triggle 1994).

Nitric oxide is a nonpolar gas and it readily crosses cellular membranes, providing access to intracellular structures in nearby cells. Unlike classical neurotransmitters and hormones, nitric oxide does not seem to require a specific macromolecular protein for its receptor site. Nitric oxide is oxidized rapidly upon contact with oxygen, yielding the much less active nitrites and nitrates. Alternatively, nitric oxide can interact with the heme constituent of iron-containing enzymes, leading to configurational modifications that adjust catalytic activity of the affected enzyme.

Activation of cytosolic guanylyl cyclase through nitrosation of its heme moiety is considered a cardinal mechanism of action of nitric oxide in platelets and smooth muscles. The resulting increase in cGMP is the intracellular messenger subserving the physiologic response to nitric oxide (Fig. 5.8). Smooth muscle relaxation and anti-platelet-aggregating actions of nitric oxide are mimicked by cell-permanent forms of cGMP and are potentiated by inhibitors of the cGMP phosphodiesterase enzyme. Activation of quanylyl cyclase by nitric oxide not only is responsible for dilation of blood vessels and inhibition of thrombogenesis but is involved in neuronal signaling and cytotoxicity responses to nitric oxide as well.

Because of amino acid heterogenicity in the structural motif of the different isoforms of NOS, the following nomenclature modification has been proposed: the neuronal cNOS has been referred to as NOS-I, the macrophage iNOS as NOS-II, and the endothelial cNOS as NOS-III. This nomenclature will no doubt continue to evolve as new discoveries are made.

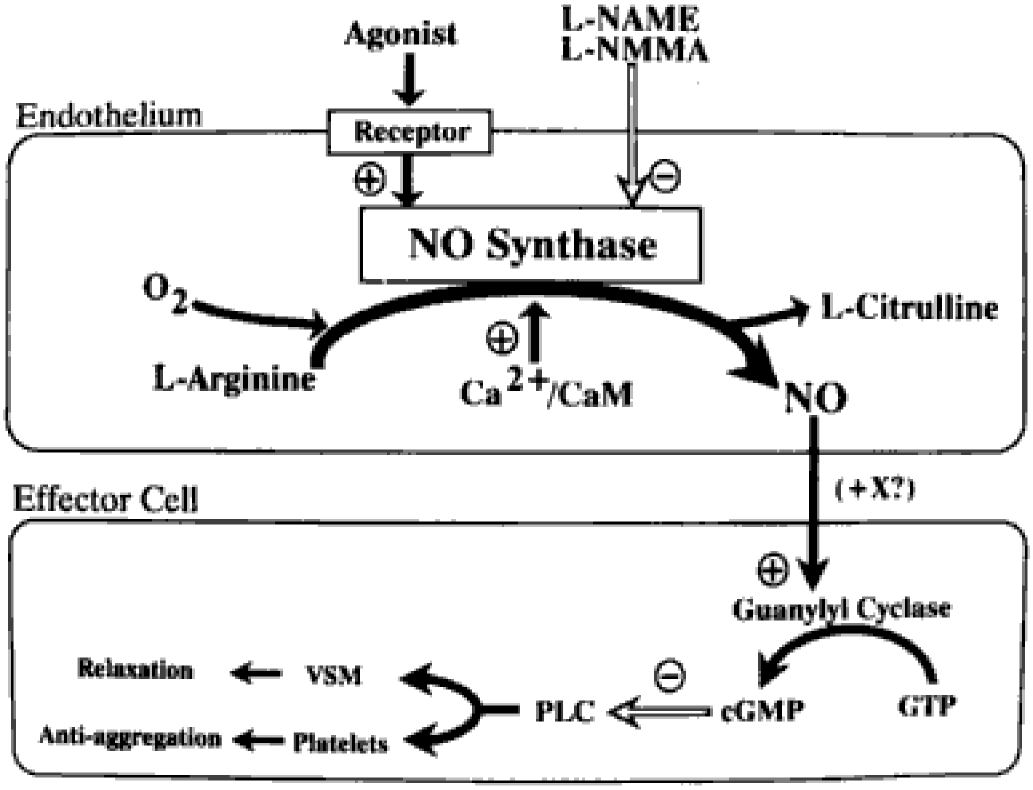

FIG. 5.8—The biosynthetic pathway for nitric oxide (NO) in vascular endothelial cells. Increased intracellular Ca^{++} activates the Ca^{++}-calmodulin (CaM)-dependent enzyme NO synthase, which utilizes O_2 and L-arginine to form NO. NO activates guanylyl cyclase in nearby platelets and vascular smooth muscle (VSM), leading to increased formation of cyclic guanosine monophosphate (cGMP). The latter inhibits phospholipase C (PLC) and exerts other effects that lead to changes in cellular functions, e.g., vasodilation and antiaggregation of platelets. L-arginine analogs such as L-nitroarginine methylester (L-NAME) and L-nitromonomethyl arginine (L-NMMA) inhibit NO synthase. (+X?) = possible biological carrier of NO. ⊖ = activates; ⊕ = inhibits.

Pharmacologic Modulation of Nitric Oxide Synthesis and Action. Organic compounds containing nitrate or nitroso moieties such as nitroglycerine, nitroprusside, *S*-nitroso-*N*-acetylpenicillamine, $NaNO_2$, and sydnonimines undergo tissue-catalyzed metabolism or spontaneous breakdown to yield exogenous-source nitric oxide. These and related compounds serve as nitric oxide donors, and their pharmacodynamic actions mimic in many respects the physiologic effects of endogenously synthesized nitric oxide.

There are several different types of NOS inhibitors, including congeners of the substrate L–arginine. The N^G-substituted L-arginine analogs include *N*-nitro-L–arginine methylester (L–NAME), *N*-nitro-L–arginine, and *N*-methyl-L–arginine (L–NMA). These inhibitors generally are competitive when administered concomitantly with L-arginine, and studies are under way to identify arginine analogs that are more selective for either iNOS or cNOS. Arginine analogs are routinely described as "specific" inhibitors of NOS, and yet few studies have systematically tested whether these agents also possess pharmacologic actions unrelated to NOS inhibition. In this regard, for instance, recent studies have indicated that L–NAME is a muscarinic receptor antagonist and may therefore inhibit effects of ACh by muscarinic receptor blockade. As another example, apparently L–NMMA) can be metabolized to L–arginine and actually accelerate NOS activity under some circumstances. Such pharmacologic limitations should be considered when drugs are assumed to be "specific" inhibitors of NOS.

Other inhibitors of NOS include calmodulin antagonists for cNOS, flavoprotein binders for iNOS and cNOS, heme binders such as carbon monoxide for iNOS and cNOS, and inhibitors of iNOS induction. Inhibitors of iNOS induction include corticosteroids and certain cytokines such as transforming growth factor-α and interleukins-4 and -10. Although tumor necrosis factor-α is a strong inducer of iNOS, recent experiments indicate this cytokine may inhibit synthesis or accelerate breakdown of cNOS.

Physiologic Roles Proposed for Nitric Oxide. Proposed physiologic roles for nitric oxide undergo dynamic revision almost weekly, and many areas overlap. The following points are quite selective but provide a brief glimpse of the wealth of bodily functions that may be modulated by nitric oxide.

CIRCULATION. The discovery of EDRF initially focused interest on endothelial cell cNOS as a source of vasodilatory nitric oxide. Indeed, as mentioned previously, basal release of EDRF is a primary determinant of vasodilation and blood flow through vascular networks, including coronary, cerebral, renal, and skeletal muscle arteries. Release of nitric oxide from endothelial cNOS is stimulated not only by certain receptor agonists but also by shear stresses exerted over the intimal surface by flowing blood. Nitric oxide from endothelial cNOS participates in vascular autoregulatory control mechanisms, e.g., in hypoxia-induced vasodilation and metabolic demand–induced vasodilation associated with ischemia-reperfusion.

Recent studies have shown that immunomodulatory-inflammatory stimuli can induce an iNOS in both endothelium and vascular smooth muscle. Thus, nitric oxide derived from both the intimal layer and the blood vessel wall may play important pathophysiologic roles in the local circulatory response to infection and inflammation (Parker and Adams 1993).

Nitric oxide exerts antiaggregating actions in platelets, thereby eliciting thrombolytic or antithrombogenic effects. Inhibition of aggregation is not restricted to platelets; nitric oxide also slows leukocyte adhesion and aggregation onto the vascular intimal surface. Inhibition of platelet aggregation and adhesion by nitric oxide is believed to be an important constituent of the antithrombogenic characteristic of the intimal surface of the blood vessel lumen. Impaired synthesis of nitric oxide has been implicated in the formation of atherosclerosis and the affiliated loss of vasodilator function.

NEUROTRANSMITTER. Nitric oxide is believed to act as a neuronal messenger in both the central and peripheral components of the nervous system. In the brain, nitric oxide participates in experience-driven synaptic plasticity that may control learning and memory retention. Nitric oxide may well be the mediator of neuronal responses to certain excitatory amino acids. And because of its ability as a gas to be "broadcast" and diffuse from a single neuron to large numbers of nearby cells, nitric oxide may be an important controller of neuronal development and spatial orientation of neuronal centers. This exciting theory is quite distinct from the classical concept of one neuron releasing a signal molecule that interacts with specific receptor sites only on one adjacent neuron.

Peripheral neuronal control of intestinal peristalsis and synchronous opening-closing of GI sphincters has been ascribed historically to NANC nerves because the responsible neurotransmitter was unknown. It now seems that certain NANC nerves may be reclassified as nitric oxide neurons because this gas may be a NANC neurotransmitter in the alimentary tract, external genitalia, and the respiratory tract.

RESPIRATORY TRACT. There is increasing evidence that NANC nerves innervating bronchiolar smooth muscle release nitric oxide, which serves as a mediator of neurogenic bronchodilator tone. End-stage chronic obstructive pulmonary disease has been associated with decreased nitric oxide production, and it has been proposed that oxidation of nitric oxide may be accelerated in inflamed airways, leading to loss of bronchodilator reserves. Hypoxia-induced pulmonary vasoconstriction is an important compensatory reaction diverting or shunting blood flow away from nonperfused pulmonary zones and toward selective perfusion of oxygenated alveoli. Loss of this reflex may be an important component of acute respiratory distress syndrome (ARDS) and may also occur during prolonged periods of general anesthesia. Because of its conjoint bronchodilator and vasodilator activities, nitric oxide has not escaped the attention of pulmonary care centers. Inhalation of exogenous nitric oxide is undergoing evaluation as a selective vasodilator in oxygenated alveoli since inhaled gas would be delivered only to ventilated regions of the lung; this would selectively enhance perfusion only of oxygenated alveoli, thereby improving ventilation-perfusion matching.

PENILE ERECTION. Neurogenic control of penile erection is issued through the sacral division of the parasympathetic nervous system, and yet drugs that block receptors for the classical parasympathetic neurotransmitter ACh fail to prevent erection. This decades-old perplexity may have been resolved by the discovery of NANC neurons containing NOS in pelvic nerve plexuses. Immunohistochemical evidence exists that these nitric oxide neurons extend into the cavernous nerve and affect processes in the corpus cavernosum and its affiliated penile blood vessels. Functionally, pharmacologic inhibitors of NOS forestall electrically stimulated erection in animals and inhibit relaxation of corpus cavernosum smooth muscle. It has therefore been proposed that nitric oxide is the final chemical mediator controlling relaxation of corpus cavernosum smooth muscle and its supplying blood vessels, leading to vascular tumescence necessary for erection. Future studies no doubt will focus on the putative role of NOS and nitric oxide in impotence and priapism.

GASTROINTESTINAL FUNCTION. Peristalsis of the alimentary tract and synchrony of GI sphincter functions are believed to be regulated by nitric oxide released from neurons. Nitric oxide production and NOS have been localized to the enteric nerve plexuses formerly classified as intestinal NANC neurons. Nitrate concentration is elevated in diarrhea, and colonic production of nitric oxide is increased in patients with ulcerative colitis. Abnormalities of nitric oxide production have been implicated in esophageal motility disorders associated with esophageal achalasia and pyloric motility dysfunction in infantile hypertrophic pyloric stenosis. These interrelations between nitric oxide and GI function suggest more than an incidental role for nitric oxide in regulation of intestinal smooth muscle function.

G PROTEINS AND CYCLIC NUCLEOTIDES. Cyclic adenosine 3′,5′-monophosphate (cAMP), a cyclic nucleotide, acts as a "second messenger" to link

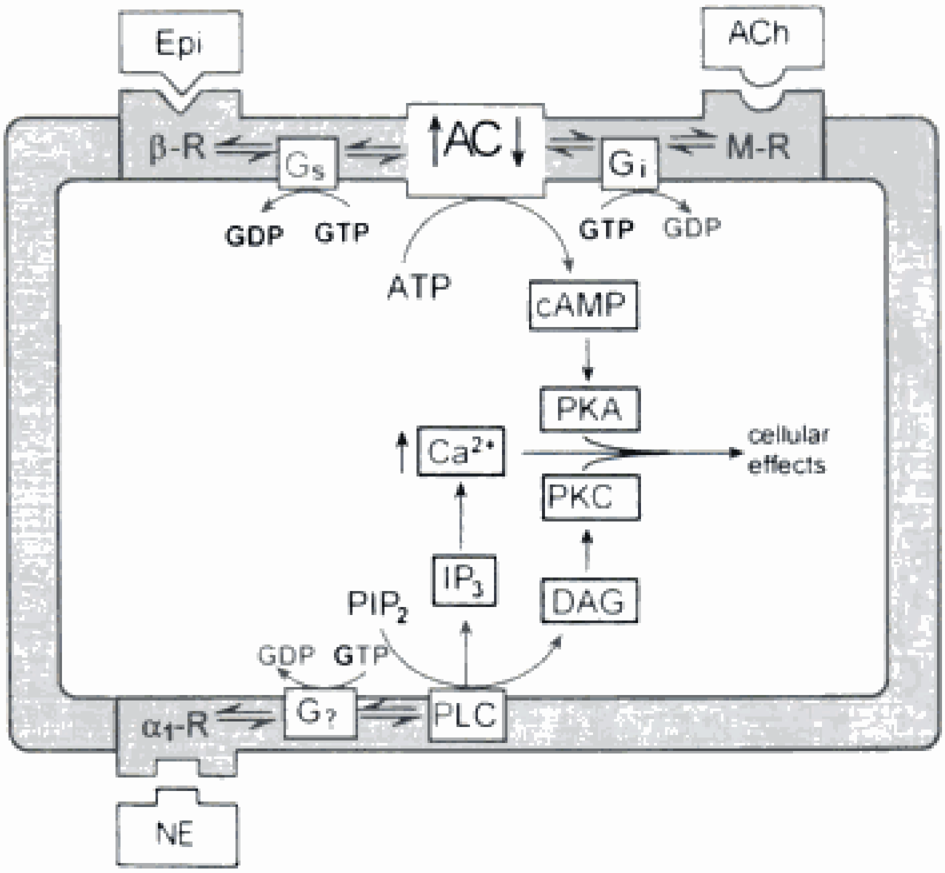

FIG. 5.9—Signal transduction pathways involving cell surface receptors (R), guanine nucleotide-binding regulatory proteins (G), and intracellular Ca^{++}. Activation of β-R by epinephrine (Epi) involves a stimulatory G (G_s), which serves as a GTPase (converting GTP to GDP) and activates the enzyme adenylyl cyclase (AC). The latter converts ATP to cyclic adenosine 3′,5′monophosphate (cAMP), which activates protein kinase A (PKA). Acetylcholine (ACh) binds with a muscarinic-R (M-R) linked to an inhibitory G (G_i), which reduces catalytic activity of AC and hence PKA. Activation of α_1-R by norepinephrine (NE) activates another G ($G_?$), which in turn activates phospholipase C (PLC). PLC hydrolyzes a membrane phospholipid phosphatidylinositol-4,5-bisphosphate (PIP_2), releasing inositol-1, 4,5-trisphosphate (IP_3) and diacylglycerol (DAG), which release endoplasmic reticulum Ca^{++} and activate protein kinase C (PKC), respectively. PKA and PKC phosphorylate various cellular constituents that, in concert with elevated cytosolic Ca^{++}, elicit characteristic changes in cellular functions. (Modeled after Lefkowitz et al. 1990; Lambert 1993; Schwinn 1993; and Levitzki et al. 1993.)

certain agonist-receptor interactions with cellular responses (Sutherland and Rall 1960; Robison et al. 1967; Robison 1971; Rall 1972). Cyclic AMP is formed from ATP by the catalytic action of the enzyme adenylyl cyclase. It is broken down to 5′-adenosinemonophosphate by another enzyme, phosphodiesterase. Adenylyl cyclase is believed to be localized in the cell membrane in mammalian cells that contain the cAMP system (Gilman 1984). Adenylyl cyclase is closely linked to numerous hormonal receptor sites, and changes in intracellular concentration of cAMP explain the pharmacologic activity of certain autonomic drugs and hormones.

It is known, e.g., that the adrenergic drugs norepinephrine, epinephrine, and isoproterenol increase the concentration of cAMP in the liver. This effect is mediated through acceleration of the activity of adenylyl cyclase. Isoproterenol, primarily a β agonist, has the greatest effect, whereas norepinephrine, primarily an α agonist, has the least potent action. These relationships correspond closely with catecholamine-mediated glycogenolysis in the hepatocytes, which has now been attributed to cAMP-mediated increase in phosphorylase activity.

Alteration of adenylyl cyclase and resultant change in cAMP by various adrenergic drugs have been demonstrated in numerous other mammalian tissues, including spleen; kidney; brain; adipose cells; and cardiac, skeletal, and smooth muscles. An increase in the tissue concentration of cAMP is generally associated with β-receptor activation, whereas a decrease in cAMP seems to be mediated in some tissues by α_2 receptors. Numerous endocrine hormones may also act via alteration of tissue levels of cAMP. In contrast, the inositol triphosphate pathway is the intracellular mechanism linked to α_1-receptor activation. The cellular pathways linking hormone receptors to guanine nucleotide-binding regulatory proteins (i.e., G proteins), cyclic nucleotides, and associated enzymes are schematized in Fig. 5.9 (also see Lambert 1993; Schwinn 1993; Levitzki et al. 1993).

The interrelationship of β adrenoceptors and cAMP has been intensely studied in heart muscle.

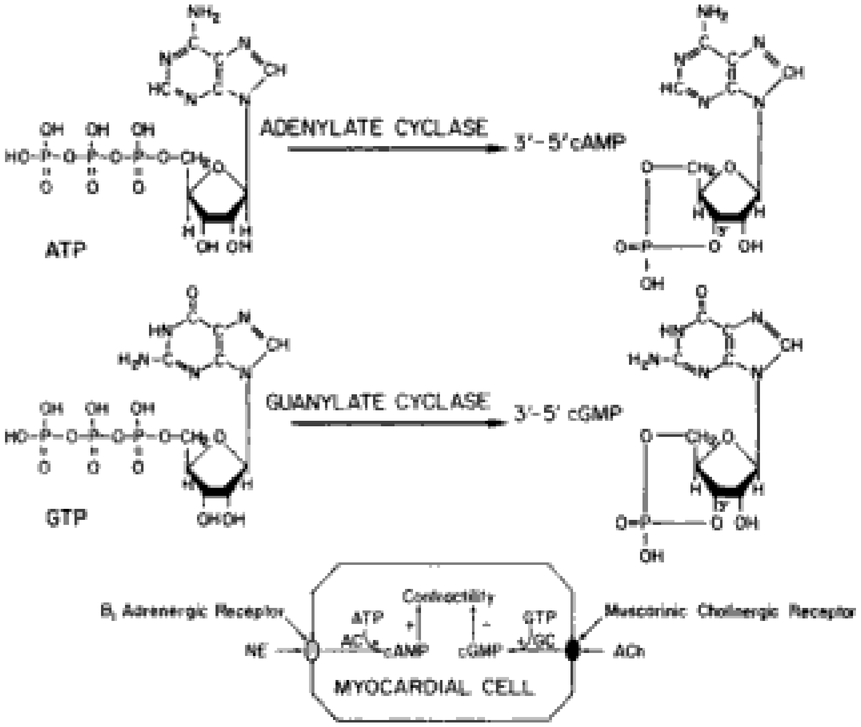

FIG. 5.10—Structures and biosynthetic pathways of cyclic AMP (cAMP) and cyclic GMP (cGMP) and a schematic of their potential roles as intracellular messengers for autonomic neurotransmitters. Activation of β-adrenergic receptors by NE increases activity of adenylate cyclase (AC), an enzyme that catalyzes (+) the conversion of ATP to cAMP. Increased intracellular cAMP leads to increased (+) contractility (via several mechanisms) of the myocardial cell. ACh activates muscarinic receptors, which leads to activation of guanylate cyclase (GC), an enzyme that catalyzes (+) the conversion of guanosine triphosphate to cGMP. Increased intracellular concentration of cGMP leads (via several mechanisms?) to decreased myocardial contractility.

Catecholamines increase the concentration of cAMP in the myocardium by activating adenylyl cyclase secondary to their agonist effects at the cardiac β_1 adrenoceptors. Increases in cAMP correspond with an increase in heart rate and contractile strength, and effects of catecholamines in the heart are mediated by the formation of cAMP.

Several groups of drugs have been known to elicit autonomic-like activity in various tissues, but attempts to associate these effects with change in neurohumoral transmission have failed. It now seems that certain of these drugs bypass receptor sites and act on the same cAMP system as the catecholamines. The methylxanthines (caffeine, theobromine, theophylline), e.g., elicit changes in heart function reminiscent of β-receptor activation in that they elicit positive inotropic and chronotropic responses. However, β blockers do not prevent the cardiac actions of the methylxanthines. These drugs are phosphodiesterase inhibitors. By inhibiting the phosphodiesterase enzyme, the catabolism of cAMP is impaired and the cellular concentration of this nucleotide increases. Furthermore, the methylxanthines potentiate the effect of catecholamines and other drugs that activate adenylyl cyclase (Samir Amer and Kreighbaum 1975).

Another related nucleotide, cyclic guanosine 3′,5′-monophosphate (cGMP), is also important as an intracellular messenger in some cell types (Robison 1971). Specifically, cGMP is the second messenger for the effects of ACh mediated through activation of the muscarinic receptor. The structures and biosynthetic pathways of cAMP and cGMP are presented in Fig. 5.10 along with a model of their potential antagonistic actions on myocardial contractility (George et al. 1975; Nawrath 1976).

AUTONOMIC DRUGS. Drugs that exert pharmacologic effects simulating activation, intensification, or inhibition of either the sympathetic or the parasympathetic nervous system have been historically referred to as autonomic drugs. As a rule, autonomic drugs are classified according to the physiologic activity they mimic. Table 5.2 summarizes the classification of the basic types of autonomic drugs that will be discussed in subsequent chapters.

TABLE 5.2—Classification of autonomic drugs

Classification	Other terms	Pharmacologic effects	Mechanisms and examples
Sympathomimetic	Andrenergic[*] Adrenomimetic[*]	Resemble effects caused by stimulation of adrenergic neurons Simulate effects of epinephrine and norepinephrine	Direct acting—α,β-adrenergic receptor agonists (α-phenylephrine; β-isoproterenol; α,β-epinephrine) Indirect acting—release endogenous stores of catecholamines (tyramine, amphetamine) Increase sympathetic discharge (nicotinic cholinergic agonists)[†]
Sympatholytic			
Receptor blocking effects	Adrenergic blocking drugs	Inhibit effects of sympathomimetic drugs; inhibit responses caused by stimulation of adrenergic neurons	Block α or β receptors (α blocker—phentolamine; β blocker—propranolol)
Neuronal blocking effects	Adrenolytic	Inhibit responses caused by stimulation of adrenergic neurons	Deplete endogenous catecholamines (reserpine) Inhibit release of morepinephrine from nerve terminals (bretylium)
Parasympathomimetic	Cholinergic[§] Cholinomimetic[§]	Resemble effects caused by stimulation of postganglionic parasympathetic neurons Simulate effects of ACh	Direct acting—cholinergic receptor agonists (ACh, carbachol) Indirect acting—cholinesterase inhibitors (neostigmine, organophosphates)
Parasympatholytic			
Receptor blocking effects	Cholinergic[§] blocking drugs	Inhibit effects of ACh; inhibit responses caused by stimulation of postganglionic parasympathetic neurons	Block nicotinic[§] or muscarinic receptors (muscarinic blocker—atropine; nicotinic blocker—hexamethonium)
Neuronal blocking effects	Anticholinergic[§]	Inhibit responses caused by stimulation of postganglionic parasympathetic neurons	Inhibit release of ACh from nerve terminals (botulinum toxin)

[*] These terms refer specifically to activities at adrenergic synapses, adrenergic neuroeffector junctions, and adrenergic receptors.

[†] Sympathomimetic effects may be produced by nicotinic cholinergic agents by their excitatory action on sympathetic ganglia, the adrenal medulla, and adrenergic nerve terminals, causing sympathetic discharge and release of epinephrine and norepinephrine. However, these activities should be considered as secondary when broad-based classifications of autonomic drugs are considered.

[§] These terms also refer to nonautonomic sites (e.g., somatic neuromuscular junction, CNS). Thus the terms parasympathomimetic and parasympatholytic are reserved to describe activities at the parasympathetic neuroeffector junction (i.e., in relation to muscarinic receptors; see text).

  Miscellaneous Agents

Amine substances that cause physiologic responses similar to those evoked by the endogenous adrenergic mediators epinephrine and norepinephrine are known as adrenergic drugs. They are referred to as sympathomimetic agents because their pharmacologic effects mimic sympathetic nervous system activity. Sympathetic neurons and affiliated receptors of innervated cells are depicted in Fig. 6.1. Most clinically relevant adrenergic agonists exert their principal pharmacodynamic actions through receptor activation. Just the opposite, adrenergic receptor antagonists prevent receptor activation and thereby reduce sympathetic activity. "Sympatholytic," "adrenolytic," and "adrenergic blocking" are terms used to describe pharmacologic effects that, in general, simulate a decrease in adrenergic nerve activity. These terms are not synonymous, and they have been used to describe different types of antiadrenergic actions, as will be discussed later in this chapter.

ADRENERGIC (SYMPATHOMIMETIC) DRUGS.

Pharmacologic effects of sympathomimetic amines are mediated by activation of adrenergic receptors of effector cells innervated by the sympathetic nervous system (Fig. 6.1). Noninnervated adrenoceptors also are present in some cell types. In general, therefore, pharmacologic effects of adrenergic agonists can be equated to physiologic effects resulting from increased sympathoadrenal discharge. A thorough understanding of basic adrenoceptor concepts is important to the future practitioner because this information has direct application to the clinical use of all adrenergic agonists and antagonists (Adams 1984).

Adrenergic Receptors. Adrenergic receptors (i.e., adrenoceptors) are macromolecular structures localized on or within the surface membrane of cells innervated by adrenergic neurons (and certain noninnervated cells). The basic physiologic function of the adrenergic receptor is to recognize and interact with the endogenous adrenergic mediators norepinephrine and epinephrine. This interaction triggers a series of complex intracellular events that yield a characteristic change in effector cell activity.

A classic simplification of the complex field of adrenergic receptors was formulated by Ahlquist in 1948; he proposed the existence of two basic types of adrenergic receptors, which he designated as alpha (α) and beta (β). This classification system is based on the relative potencies of several adrenergic agonists to elicit excitatory and inhibitory effects in different tissues.

Structure-Activity Relationships. Several factors have complicated determination of optimal structural requirements for adrenergic drugs. Most adrenergic drugs affect both α and β receptors, and the ratio of α and β activity varies tremendously between drugs and species. Some adrenergic agents cause indirect effects mediated by release of endogenous norepinephrine. Despite these various and often conflicting interrelationships, some general and some rather specific aspects of the structure-activity relationship of sympathomimetic amines have been determined.

The basis for sympathetic-like activity of various drugs depends upon the similarity of their chemical

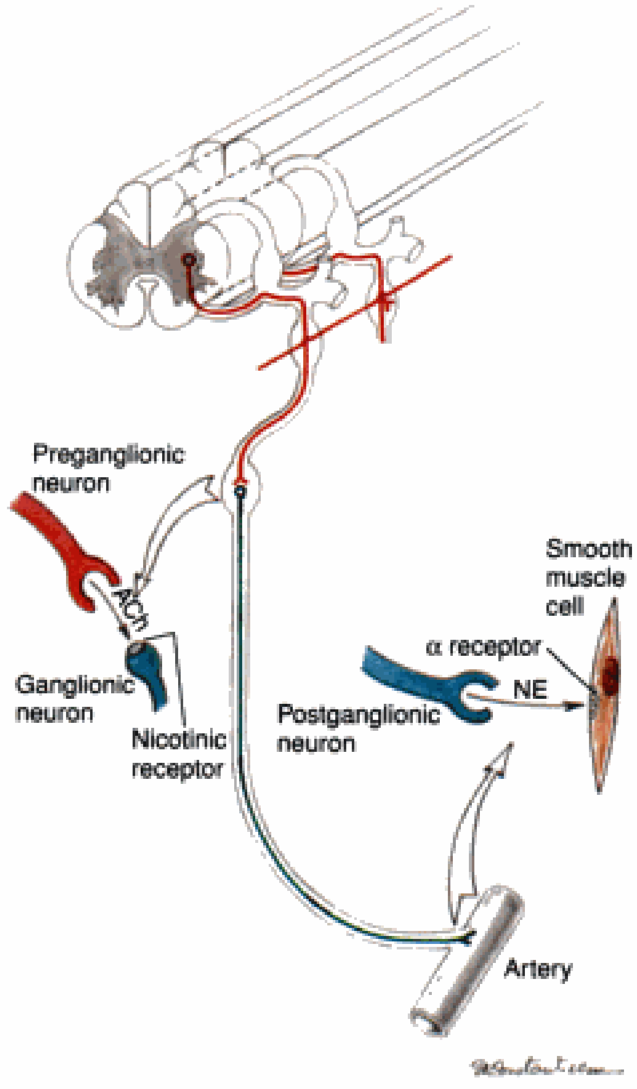

FIG. 6.1.—Anatomical relationships of sympathetic neuronal outflow tracts and affiliated receptors of innervated cells. Sympathetic preganglionic axons exit the thoracolumbar region of the spinal cord and synapse with ganglionic neurons in an adjacent ganglion, or pass through the latter to synapse with a neuron within a distant ganglion (shown). The preganglionic axon terminal releases the neurotransmitter acetylcholine (ACh), which activates nicotinic cholinergic receptors on the ganglionic neuron body. The resulting stimulation of the ganglionic neuron promotes release of the neurotransmitter norepinephrine (NE) from the axon terminal at the postganglionic sympathetic neuroeffector junction at blood vessels (shown) or other tissues innervated by sympathetic neurons. NE activates α- (shown) or β-adrenergic receptors present on cells innervated by the sympathetic division of the autonomic nervous system. Preganglionic fibers are red; postganglionic fibers are blue. Drawn by Dr. Gheorghe M. Constantinescu, University of Missouri.

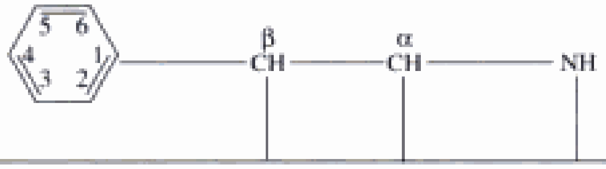
TABLE 6.1—Chemical structures and related pharmacologic activities of some commonly used sympathomimetic amines



Drug		β CH	α CH	NH	Activity	Clinical use
β-phenylethylamine	. . .	H	H	H	. . .	. . .
β-phenylethanolamine	. . .	OH	H	H	. . .	. . .
Catecholamines						
Dopamine	3-OH, 4-OH	H	H	H	α, β_1, D	P, C, K
Norepinephrine	3-OH, 4-OH	OH	H	H	α,β_1	P, C
Epinephrine	3-OH, 4-OH	OH	H	CH_3	α, β	P, C, A, B
Isoproterenol	3-OH,4-OH	OH	H	$CH(CH_3)_2$	β	C, B
Noncatecholamines						
Metaraminol	3-OH	OH	CH_3	H	α	P
Phenylephrine	3-OH	OH	H	CH_3	α	P, Rb
Tyramine	4-OH	H	H	H	I	. . .
Hydroxyamphetamine	4-OH	H	CH_3	H	I	CNS
Amphetamine	. . .	H	CH_3	H	I	CNS
Methamphetamine	. . .	H	CH_3	CH_3	I	CNS
Ephedrine	. . .	OH	CH_3	CH_3	I, α, β	P, C, CNS

Note: α = α receptor; β = β receptor; A = allergic reactions; B = bronchodilator (β_2 receptor); C = cardiac stimulation (β_1 receptor); CNS = central nervous system excitation; D = dopamine may interact with α, β_1, and dopaminergic receptors; I = indirect-acting, causes release of endogenous norepinephrine that acts on α and β receptors; K = renal vasodilation (dopaminergic receptors); P = pressor activity; Rb = reflex bradycardia from pressor activation of baroreceptor-vagal reflex.

subserve an autoinhibitory regulation of norepinephrine release mechanisms. The physiologic role of α-receptor prejunctional events is envisioned as a local servomechanism through which norepinephrine can govern its own release once a threshold concentration of transmitter has been exceeded within the junction (Saeed et al. 1982).

PREJUNCTIONAL β Receptors. Epinephrine also can activate the prejunctional autoinhibitory α receptors, with potency about equal to that of norepinephrine. Interestingly, however, low concentrations of epinephrine actually accelerate norepinephrine release. This facilitatory action is shared by the β agonist isoproterenol and prevented by β-blocking drugs. These findings indicate that noradrenergic nerve endings possess β receptors that subserve a stimulatory effect on transmitter release mechanisms, an action opposite to that of the prejunctional α receptor.

Norepinephrine itself seems to have little influence on the prejunctional β-autostimulatory receptors, perhaps because this receptor population is more representative of β_2 rather than β_1 subtype. Thus the α-controlled autoinhibitory cycle probably dominates during usual communication between neuron and effector cell. A model of noradrenergic neurohumoral transmission incorporating prejunctional α and β receptors is presented in Fig. 6.2, along with representative effector cells, their prototypical receptor classes, and associated physiologic responses (Adams 1984).

ADRENERGIC RECEPTOR CLASSIFICATION. The original differentiation of adrenergic receptors into the two main classes, α and β, was based mainly on the relative potencies of the agonists norepinephrine, epinephrine, and isoproterenol in eliciting excitatory or inhibitory effects in a series of tissues (e.g., heart, vasculature, lungs) (Ahlquist 1948). Excitatory responses were generally designated as α-receptor events, and, for the most part, inhibitory responses were designated as β-receptor events. The excitatory β receptors of the heart represented an important exception to this rule and pointed toward different types of β receptors.

β_1-β_2 ADRENERGIC RECEPTOR SUBTYPES. Partly because of the potent β-stimulatory properties of norepinephrine in some tissue (e.g., the heart), but not others (e.g., the lungs), it was suggested that β receptors actually comprised a heterogeneous population of two distinct subtypes: β_1 and β_2 (Lands et al. 1967). Many tissues contain both β_1 and β_2 receptors in various ratios, depending on species and other variables. One subtype usually dominates and provides the tissue and organ with their functional classification as being under either β_1 or β_2-receptor control. A compilation of the predominant β-receptor subtype in several tissues is included in Table 5.1.

CARDIAC β_1 RECEPTORS. The functionally prevalent β receptor in the myocardium of most if not all mammalian species is the β_1 subtype. These receptors are activated in the following order of potency: isoproterenol > epinephrine ≥ norepinephrine. Activation of cardiac β_1 receptors leads to the characteristic sympathomimetic response of the heart as schematized in Fig. 6.3. In brief, this entails positive inotropic effects

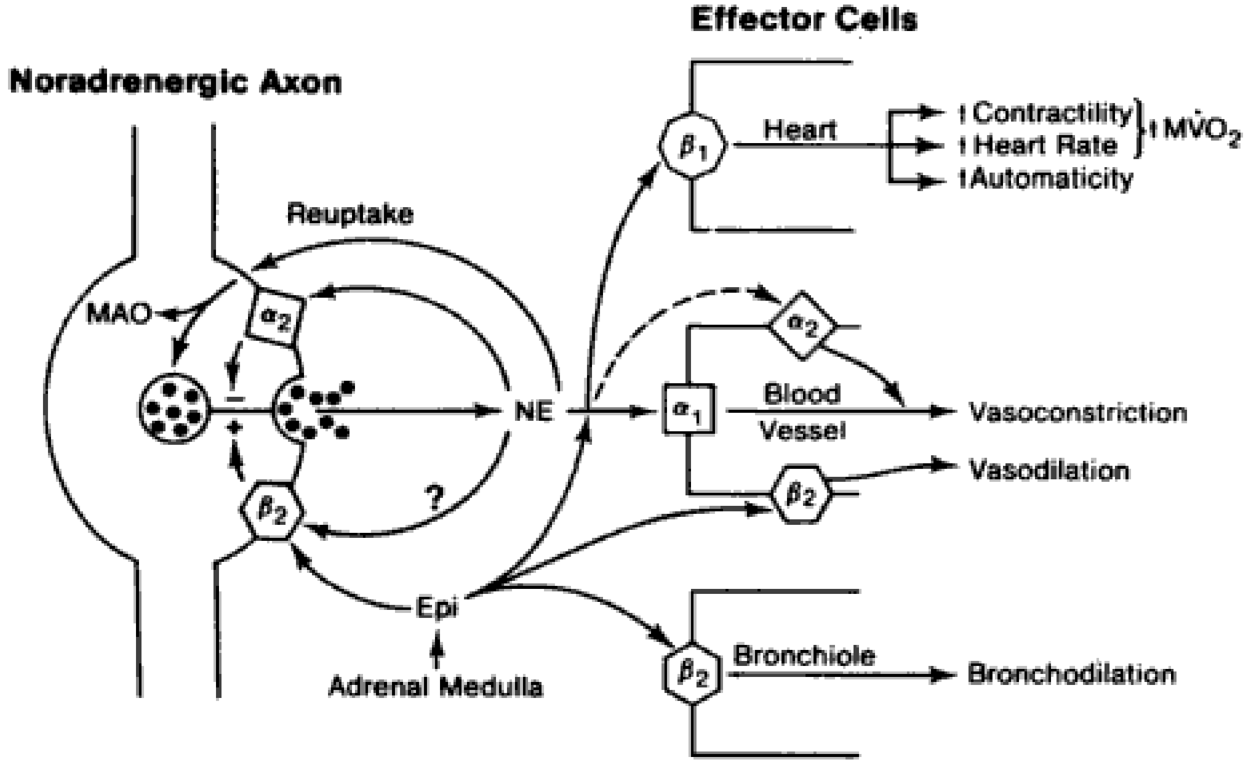


FIG. 6.2—Schematic diagram of peripheral noradrenergic neuroeffector junctions with a model axon terminal varicosity on the left and typical effector cells on the right. The predominant adrenoceptor subtypes and associated physiologic responses of the heart, blood vessel, and bronchiole are depicted. Norepinephrine (NE) released from the neuron can interact postjunctionally with innervated α_1 or β_1 receptors of effector cells and perhaps overflow (dashed line) to other nearby postjunctional receptors. NE also can activate prejunctional α receptors (α_2 subtype) to inhibit further release of NE. NE is removed from the junctional cleft by diffusion, extraneuronal uptake, and active uptake (reuptake) into the neuron, where it is metabolized by monoamine oxidase (MAO) or reincorporated into storage vesicles. Prejunctional β receptors (β_2 subtype) subserve a facilitatory effect on NE release, but it is questionable (?) whether NE itself activates this β_2-autostimulatory feedback loop. NE also has little β_2-agonist activity in blood vessels or bronchioles, whereas epinephrine (Epi) can activate all types of α and β adrenoceptors. $\dot{M}VO_2$ = myocardial oxygen demand (Adams 1984).

(increased contractility), positive chronotropic effects (increased heart rate), positive dromotropic effects (accelerated conduction of the cardiac impulse), and emergence of latent pacemaker activity. Increased heart rate and contractility lead in turn to increased myocardial oxygen demand and metabolic coronary vasodilation.

PULMONARY AND VASCULAR SMOOTH MUSCLE β_2 RECEPTORS. The β-adrenergic receptors of the pulmonary airways and peripheral vascular beds are mainly the β_2 subtype (Fig. 6.2). These receptors are activated potently by isoproterenol and epinephrine but quite poorly by norepinephrine. The β_2-pulmonary receptors subserve relaxation of bronchiolar smooth muscle and its accompanying bronchodilation, leading to an improvement in airway conductance. Vascular smooth muscle β_2 receptors are present in various tissues, where they mediate vasodilation and reduced vascular resistance. Although there is some uncertainty, most β_2-vascular receptors are probably noninnervated and, as with the pulmonary β_2 receptors, depend mainly on circulating epinephrine for activation and basal adrenergic tone (Fig. 6.2).

α_1-α_2 RECEPTOR SUBTYPES. Alpha receptors also can be divided into two distinct subpopulations: α_1 and α_2. This nomenclature began with the realization that the prejunctional α-receptor population responded to drugs somewhat differently than did the usual α receptors of effector cells. This led to classification of the typical effector cell α receptor as α_1 subtype, while the nerve terminal receptor was designated as α_2 (Fig. 6.2).

Alpha$_2$ receptors are not restricted anatomically to neuronal elements. They also are located on some noninnervated cell types, e.g., thrombocytes. Moreover, α_2 receptors also share certain tissue and functions with the α_1 subgroup. Pressor responses mediated by norepinephrine and epinephrine, e.g., involve activation of α_1- and α_2-receptor types in vascular smooth muscle. The α_1 receptor represents the innervated vascular receptors, whereas the α_2 type in this tissue is believed to localize predominantly in extrasynaptic regions of vascular smooth muscle cells. Endothelial cells of blood vessels also have α_2 receptors, which subserve release of endothelium-derived relaxing factor (EDRF) leading to vasodilation. EDRF has been identified as nitric oxide or a closely related compound that releases

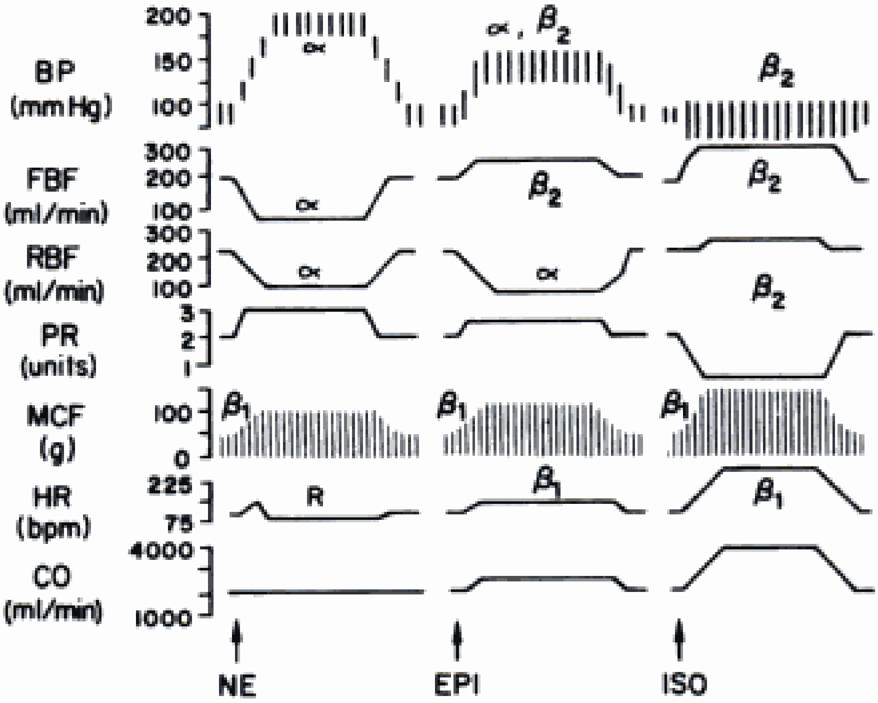

FIG. 6.3—Cardiovascular effects of intravenously administered norepinephrine (NE), epinephrine (Epi), and isoproterenol (ISO) in a dog. Schematic representations of effects of equivalent doses of these amines on blood pressure (BP), femoral blood flow (FBF), renal blood flow (RBF), peripheral vascular resistance (PR), myocardial contractile force (MCF), heart rate (HR), and cardiac output (CO). α = response mediated primarily by α-adrenergic receptor; β = response mediated primarily by β-adrenergic receptor (β_1 or β_2 subtype); R = reflex mediated. Characteristics of cardiovascular excitation evoked by these agents are due to differences in their α-β agonistic properties (Table 6.2). See text for explanation of each response.

nitric oxide (see Chap. 5; Lowenstein et al. 1994; Änggard 1994).

Based on the foregoing summary of α_1-α_2 and β_1-β_2 receptor subtypes and respective tissue responses, it should be apparent that all adrenergic drugs do not necessarily produce identical effects. Their pharmacologic profiles vary depending upon their basic chemical structure and resulting activities as α, β, or mixed α-β agonists. Nevertheless, sympathomimetic amines exhibit many similar pharmacodynamic properties. Therefore, only representative adrenergic drugs will be examined in detail; other agents will be compared in relation to differences they may exhibit in agonistic properties (i.e., activity at α or β receptors) and in mechanisms of action (i.e., direct- or indirect-acting sympathomimetic activity).

It also is important to realize that the α_1-α_2 and β_1-β_2 classification of receptors is an oversimplification of receptor subtypes. There are multiple subtype divisions of α_1, α_2, β_1, and β_2 receptors (Alberts 1993; Feldman 1993; Barnes 1993). However, the clinical relevance of adrenergic receptor classifications beyond α_1-α_2 and β_1-β_2 remains to be clarified.

CATECHOLAMINES. Catecholamines are direct-acting sympathomimetic amines. They activate receptors of effector cells; therefore, adrenergic nerves are not required for their effects.

Epinephrine, Norepinephrine, and Isoproterenol. Epinephrine (adrenaline) and norepinephrine (noradrenaline, levarterenol, arterenol) are endogenous biogenic amines; isoproterenol (isopropylarterenol) is not found in the body but is chemically synthesized. Subtle differences in the pharmacologic effects of structurally related adrenergic drugs can be demonstrated by comparing cardiovascular effects of these three agents, as shown schematically in Fig. 6.3.

Different cardiovascular responses seen with epinephrine, norepinephrine, and isoproterenol in Fig. 6.3 are due to differences in the ratios of their α- and β-agonistic properties. Classification of adrenergic receptors in the heart and blood vessels, related effects, and the order of potency of epinephrine, norepinephrine, and isoproterenol are shown in Table 6.2.

Norepinephrine, because of its α-agonist properties, activates the α-vascular receptors, resulting in intense vasoconstriction; peripheral resistance increases and femoral and renal blood flows decrease (Fig. 6.3).

Although epinephrine is a potent α stimulant, it also is very active at β receptors. Beta$_2$ receptors in blood vessels subserve vasodilation. In response to epinephrine, vasoconstriction occurs in vascular beds that have predominantly α receptors (e.g., abdominal viscera); however, vasodilation can occur in beds that contain β_2 receptors (e.g., skeletal muscle). Blood flow increases in areas in response to regional vasodilation (e.g.,

TABLE 6.2—Adrenergic receptor activation by catecholamines

Receptor type	Tissue	Response	Potency of agonists
α	Blood vessels	Vasconstriction	Epinephrine > norepinephrine >>> isoproterenol
β_1	Heart	Positive inotropic and chronotropic effects	Isoproterenol > epinephrine ≧ norepinephrine
β_2	Blood vessels	Vasodilation	Isoproterenol > epinephrine >>> norepinephrine

Note: > = greater than; ≧ = greater than or equal; >>> = many times greater.

femoral flow) but decreases if vasoconstriction dominates (e.g., renal flow) (Fig. 6.3).

Because isoproterenol is a selective β agonist, it causes vasodilation, fall in diastolic blood pressure, decrease in peripheral resistance, and increase in blood flow to areas containing β receptors (e.g., femoral blood flow). The renal vasculature has few β receptors and is therefore little affected by isoproterenol (Fig. 6.3).

The heart is activated by epinephrine, norepinephrine, and isoproterenol (Fig. 6.3). Isoproterenol is the most potent of the three and causes a relatively greater increase in myocardial contractile force, heart rate, and cardiac output than the similarly acting epinephrine. Norepinephrine also increases myocardial contractile force, but bradycardia occurs at the peak pressor effect of this amine. This is due to an increase in vagal tone reflexly instigated by the pronounced norepinephrine-induced increase in mean blood pressure. Norepinephrine-mediated peripheral vasoconstriction may decrease venous return so cardiac output does not increase, although the heart is activated.

These examples demonstrate differences in selective cardiovascular effects of these closely related catecholamines. Nevertheless, it should be apparent that all three agents elicit the same basic result, a net increase in cardiovascular activity.

PHARMACOLOGIC EFFECTS

BLOOD PRESSURE. Norepinephrine administered intravenously either by slow infusion or bolus injection causes a dose-related increase in systolic and diastolic blood pressures due to bodywide vasoconstriction. Mean blood pressure increases accordingly; little change is seen in pulse pressure.

Slow intravenous (IV) infusion of small amounts of epinephrine usually causes a fall in diastolic blood pressure that may or may not be accompanied by a slight increase in systolic pressure. This response is due to regional vasodilation (β_2-receptor-mediated), which causes a decrease in peripheral resistance. However, a bolus IV injection of a large amount of epinephrine (e.g., 1-3 μg/kg) causes a pronounced increase in blood pressure that is as remarkable as that produced by norepinephrine. It should be appreciated that epinephrine is an extremely potent pressor agent. This pressor response depends upon vasoconstriction, myocardial stimulation, and tachycardia. Bradycardia can occur at the peak pressor response as a result of reflex vagal activity. A depressor effect may be observed after the pressor response to a large dose of epinephrine. This secondary response is related to residual activation of β_2 receptors in blood vessels.

Following a single bolus injection of norepinephrine or epinephrine, the pressor response lasts for several minutes, then gradually decreases and returns to normal within 5-10 minutes. Isoproterenol increases pulse pressure predominantly by lowering diastolic pressure. This effect is due to β_2-receptor-mediated vasodilation.

VASCULAR SMOOTH MUSCLE. This type of tissue can contain both α_1- and α_2-receptor subtypes (which subserve vasoconstriction) and β_2 receptors (which subserve vasodilation). Epinephrine and norepinephrine are very potent constrictors of cutaneous and mucosal blood vessels in mammalian species. Adrenergic receptors in these vessels are almost exclusively α. Intense vasoconstriction, increased vascular resistance, and decreased blood flow occur in these regions in response to norepinephrine and epinephrine. This is often seen as a blanching type response in skin or mucosal membranes.

Since epinephrine is a more potent α agonist than norepinephrine, it is 2-10 times more active than norepinephrine in constricting cutaneous and mucosal vessels. Smaller arterioles and precapillary sphincters are particularly responsive to the vasoconstrictor catecholamines. They are active regardless of whether they are applied topically to blood vessels, sprayed upon mucosal surfaces, injected perivascularly, or administered systemically. Isoproterenol has little if any effect on cutaneous and mucosal vessels, because of the relative lack of β receptors in these tissues.

The renal vasculature has predominantly α receptors. Epinephrine and norepinephrine cause vasoconstriction in the kidney and a generalized increase in vascular resistance in this organ. Renal blood flow is decreased even in the presence of an elevated systemic blood pressure (Fig. 6.3). Large doses of α-agonistic catecholamines may actually induce a functional renal shutdown caused by decreased perfusion of the kidney. During this period, urinary output is substantially decreased from lowered glomerular filtration rate.

Isoproterenol has little effect on renal arteries because of the small number of β receptors in kidney vasculature. However, direct injection of the drug into the renal artery increases renal blood flow. In addition, there are β_1 receptors in the kidney, which upon activation cause a release of renin into the circulation for angiotensin formation.

Mesenteric arteries are constricted by norepinephrine and epinephrine as a result of activation of α receptors. Mesenteric arterial resistance is markedly increased and splanchnic blood flow decreases proportionately. In some circumstances, i.e., with small doses, epinephrine may cause slight vasodilation of splanchnic arteries because of the presence of β_2 receptors.

Skeletal muscle blood vessels have both α and β receptors. Vasoconstriction or vasodilation can be induced, depending upon the α- and β-agonistic profiles of a vasostimulatory amine. Norepinephrine, because of its relative lack of effect on β-vascular receptors, elicits vasoconstriction in skeletal muscles caused by activation of α receptors. Vascular resistance increases and blood flow decreases proportionately.

Beta receptors in skeletal muscle blood vessels are more sensitive to epinephrine than are the α receptors. Therefore, small amounts of epinephrine actually cause a decrease in vascular resistance and an increase in blood flow to voluntary muscles through vasodilation. However, large doses of epinephrine cause vasoconstriction in skeletal muscles from the α-receptor-mediated contraction overriding β-mediated relaxation. If α receptors are blocked, the response to epinephrine is converted to vasodilation from unmasking of the β effect. If a β blocker is used, the α-mediated constrictor effects of epinephrine are accentuated.

Isoproterenol causes relaxation of skeletal muscle blood vessels, increased blood flow to voluntary muscle masses, and decreased vascular resistance in these structures caused by activation of the vascular β receptors. Since isoproterenol has little effect on α receptors, β blockade abolishes the vasodilator effect of isoproterenol but does not convert the response to vasoconstriction.

Coronary arteries dilate in response to catecholamines (isoproterenol > epinephrine ≥ norepinephrine). The major portions of this vasodilator response are secondary to increased myocardial contractility and heart rate and resulting metabolic demands of the heart. Alpha receptors that subserve vasoconstriction can be demonstrated in the coronary vasculature; however, they are more prevalent in larger vessels than in smaller nutrient arteries. Beta receptors dominate, causing vasodilation and increased coronary blood flow in response to catecholamines. Studies with isolated vessels suggest that coronary receptors are of the β_1 subtype (Cornish and Miller 1975), while in vivo studies indicate the β_2 subtype (Moreland and Bohr 1984). This is different from most other vasodilator β receptors that have generally been characterized as β_2, irrespective of in vivo or in vitro setting.

Cerebral arteries are less responsive to adrenergic agonists than most other vascular beds. This is compatible with the concept that cerebral blood flow, like coronary blood flow, is controlled principally by local metabolic needs rather than by the nervous system. Nevertheless, both α-vasoconstrictor and β-vasodilator receptors can be demonstrated in cerebral blood vessels.

VASCULAR MECHANISMS. Mechanical function of a vascular smooth muscle cell depends upon the availability of free intracellular Ca^{++} in the vicinity of contractile proteins. Norepinephrine and epinephrine produce vascular contraction by initially causing release of an intracellular (sequestered) source of Ca^{++} to the contractile proteins in response to activation of α_1 receptors. The signal-transduction mechanism linking α_1 receptors to vasoconstriction involves the G protein, phospholipase C, and inositol triphosphate pathway (Brodde and Michel 1992).

Cyclic adenosine 3′,5′-monophosphate (cAMP) is increased in response to β_2-receptor activation; this mechanism utilizes the stimulatory G protein (G_s) and adenylyl cyclase pathway (Feldman 1993; Schwinn 1993; Levitzki et al. 1993) (Fig. 5.9).

MYOCARDIAL EFFECTS. Isoproterenol, epinephrine, and norepinephrine are potent myocardial stimulants. They increase the strength of myocardial contractile force and accelerate heart rate. These changes represent direct effects that are not dependent upon changes in venous return (preload), afterload, or other hemodynamic variables. Contractile and rate effects of catecholamines are mediated via direct activation of β receptors of the myocardial and pacemaker cells. Myocardial β receptors are subtyped predominantly as β_1. Isoproterenol is 10-20 times more active in the heart than epinephrine; norepinephrine is somewhat less potent than epinephrine.

The increase in myocardial contractility (positive inotropic effect) seen with each of the three agents is produced in both atrial and ventricular muscles. The positive inotropism in the whole heart is characterized by more rapid and forcible systolic ejection. The rate of pressure changes in the ventricular chambers is increased. The systolic interval is shortened and diastolic relaxation takes place more quickly. Oxygen consumption is accelerated to a relatively greater extent than the heart work is increased. Therefore, cardiac efficiency is sacrificed at the expense of absolute increase in myocardial contractility produced by catecholamines.

Acceleration of heart rate (positive chronotropism) induced by catecholamines is due to changes in the automaticity of pacemaker cells. The spontaneous depolarization process in the sinoatrial node cells is accelerated; velocity of the action potential is enhanced in these and other conduction system cells. Purkinje fibers are similarly affected by epinephrine and norepinephrine. Latent or normally inactive pacemaker cells are activated by these agents; they become more excitable and fire more easily or even spontaneously.

Norepinephrine, epinephrine, and isoproterenol increase myocardial irritability, resulting in serious tachyarrhythmias, especially in sensitized animals or with large doses. This can be partially blocked by an α blocker (Benfry 1993). However, pure α agonists such as phenylephrine and methoxamine are weak arrhythmogenic agents. Also, a β blocker such as propranolol

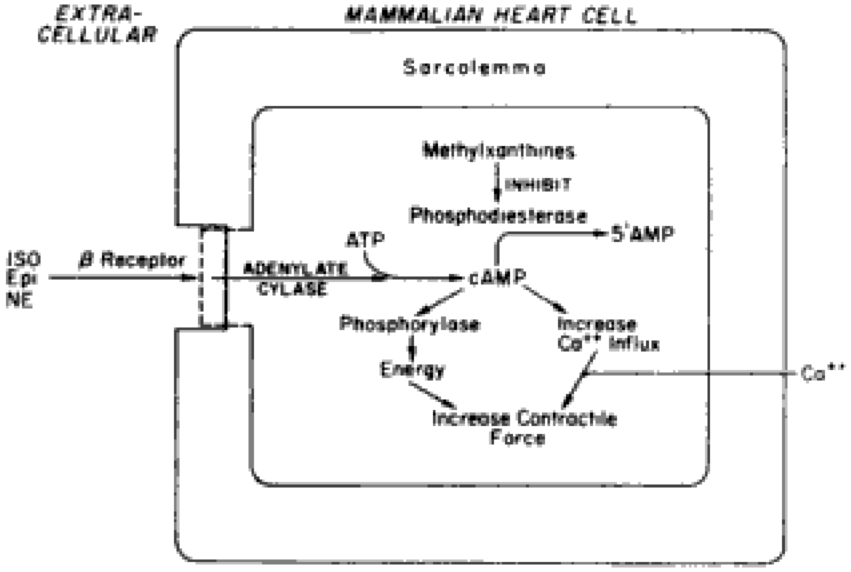

FIG. 6.4—Representation of proposed involvement of cyclic adenosine monophosphate (cAMP) in the myocardial effects of catecholamines. ISO = isoproterenol; Epi = epinephrine; NE = norepinephrine; ATP = adenosine triphosphate; 5′AMP = 5-adenosine monophosphate. The intracellular receptor for cAMP is protein kinase A, which phosphorylates different cellular substrates, resulting in changes in cell function (Feldman 1993). The stimulatory G protein (G_s) links the β-receptor recognition site to the catalytic component of adenylyl (adenylate) cyclase (Levitzki et al. 1993); see Fig. 5.9. Phosphorylase represents this and other biochemical reactions influenced by cAMP (see text).

is more active than an α blocker in decreasing the arrhythmias evoked by epinephrine and norepinephrine. Certain halogenated anesthetics (halothane, chloroform) increase the sensitivity of the heart to cardiac rhythm irregularities induced by catecholamines.

Bradycardia often occurs during the peak pressor response seen after administration of epinephrine or norepinephrine to intact animals. This can be blocked by vagotomy or atropine; it is dependent upon the hypertensive response causing an increase in vagal discharge via the baroreceptor reflex mechanisms. It is usually more pronounced with norepinephrine than with epinephrine because of the relatively greater increase in mean blood pressure seen with the former. Tachycardia is invariably produced by isoproterenol.

MYOCARDIAL MECHANISMS. In a heart muscle cell, contractile Ca^{++} is believed to originate in part from superficial sarcolemmal sites. Calcium bound at these sites is in rapid equilibrium with Ca^{++} within the extracellular space (Langer 1974; Parker and Adams 1977). Ca^{++} influx from superficial sites links membrane excitation (i.e., the cardiac action potential) to contraction of the myofibers. Catecholamines enhance the influx of Ca^{++} into the myocardial cell, due to increased intracellular concentrations of cAMP.

Activation of the cardiac β_1 receptor by epinephrine, norepinephrine, and isoproterenol increases the activity of a G_s-protein-linked adenylyl cyclase (Brodde and Michel 1992; Feldman 1993). This enzyme catalyzes the conversion of adenosine triphosphate (ATP) to cAMP. Cyclic AMP causes an increased Ca^{++} influx through the slow Ca^{++} channels of the sarcolemma, resulting in increased availability of Ca^{++} at the contractile proteins (Watanabe and Besch 1974). Cyclic cAMP activates protein kinase A, which phosphorylates various substrates, culminating in changes in cellular functions responsible for positive inotropic and chronotropic responses to β_1-receptor activation.

Several drugs alter the cAMP system in complementary ways; e.g., the methylxanthines inhibit the enzyme (phosphodiesterase) that inactivates cAMP (Fig. 6.4). These drugs, termed phosphodiesterase inhibitors, cause increase in cAMP concentrations and a positive inotropic effect in heart muscle. They potentiate inotropic activity of the catecholamines.

RESPIRATORY EFFECTS. Epinephrine is a potent bronchodilator as a result of relaxation of bronchial smooth muscle. This effect is particularly pronounced if bronchial muscle is contracted by other drugs (e.g., acetylcholine, histamine) or by anaphylactoid or asthmatic conditions. Adrenergic receptors in bronchiolar muscle are of the β_2 type. Isoproterenol is therefore a potent bronchiolar dilator, whereas exogenous norepinephrine has relatively less effect. Epinephrine and isoproterenol have been used clinically to dilate bronchiolar passageways during episodes of allergic reactions. As bronchodilators, however, selective β_2 agonists such as terbutaline and salbutamol have advantages over conventional catecholamines. The former drugs relax bronchiolar smooth muscle (β_2) with less cardiac excitatory effects (β_1) than seen with epinephrine (α-β_1-β_2 agonist) or isoproterenol (β_1-β_2 agonist), as discussed later in this chapter.

GASTROINTESTINAL SYSTEM. Adrenergic drugs inhibit gastrointestinal (GI) activity in a manner similar to that seen upon stimulation of the sympathetic nerves. The frequency and amplitude of peristaltic contractions in the gut are decreased as a result of relaxation of the intestinal smooth muscle. These effects are from activation of β-adrenergic receptors of the smooth muscle cells. Adrenergic drugs also inhibit the function of excitatory parasympathetic nerves via α_2 effects. This action contributes further to GI quiescence. Isoproterenol, as a result of β effects, exerts a rather potent inhibitory effect on GI smooth muscle. GI sphincters are generally contracted by α-sympathomimetic agents. This is in basic agreement with the overall slowing down of GI activity produced by sympathetic nerve stimulation.

Secretion of digestive juices is also decreased by α-sympathetic agents. Although salivary glands are activated in response to sympathetic activity, the saliva produced is scant and viscous, in contrast to the profuse and watery salivation seen with parasympathetic activity.

Catecholamines can exert both an inhibitory and a stimulatory effect on secretion of insulin by β cells of the pancreatic islets. The facilitatory effect is mediated via β-receptor activation, the inhibitory effect via α-receptor activation. The α-inhibitory effect is strongly predominant in vivo in most species. Since insulin is antagonistic to many of the metabolic actions of adrenergic mediators (e.g., gluconeogenesis, hyperglycemia), inhibition of insulin release by the catecholamines reinforces their metabolic effects.

Adrenergic drugs have no application as GI inhibitory agents in clinical situations. Cardiovascular effects are usually concurrently produced by dosages required to inhibit GI function. Also, parasympathetic activity in the GI system can quickly override the depressant effects exhibited by most sympathomimetic drugs.

UTERINE MUSCLE. Both α and β receptors are present in the uterus. Responses of uterine smooth muscle to catecholamines are quite variable, depending on species and stage of the estrous and gestational cycles; e.g., in the cat, epinephrine relaxes the nongravid uterus but contracts the uterus during late pregnancy. In the rabbit, epinephrine contracts the gravid and nongravid uterus. In humans, epinephrine contracts the pregnant or nonpregnant uterus when examined in vitro. In situ, however, responses vary; epinephrine may cause relaxation of the uterus during late pregnancy. Isoproterenol usually exerts relaxant effects in uterine muscle even in the presence of epinephrine-induced contraction. The presence of circulating hormones such as estrogen and progesterone modify responses of the uterus to other agents. There is presently little clinical application of catecholamines as effectors of uterine motility. However, selective β_2 agonists (e.g., salbutamol, ritodrine) have been used in human obstetrics to relax the uterus and delay premature labor.

SPLEEN. Smooth muscle of the splenic capsule is contracted by epinephrine and norepinephrine via α effects. The size of the spleen decreases and blood is discharged into the circulation. This response is probably functional in physiologic states such as acute hypoxia, severe fear or rage, hemorrhage, or other conditions that elicit a generalized activation of the sympathoadrenal axis.

The splenic effects of catecholamines are easily and decisively demonstrable in dogs anesthetized with pentobarbital. Under these circumstances, the spleen is enlarged and engorged with blood. Injection of small amounts of norepinephrine or epinephrine into the splenic artery causes a pronounced contraction of the spleen and a remarkable diminution of its size. Injection of these agents directly under the splenic capsule causes intense localized contraction of the capsule. These effects are associated with α receptors. Relaxation of the splenic capsule via β receptors also has been demonstrated.

PILOMOTOR EFFECTS. Norepinephrine and epinephrine cause contraction of piloerector muscles; hairs become erect. This effect is mediated by α receptors; it is often seen in animals during severe reaction to fear or rage.

OCULAR EFFECTS. Mydriasis occurs in response to stimulation of the sympathetic innervation to the eye. IV administration or topical application of epinephrine or norepinephrine causes pupillary dilation via α effects. Parasympathetic activity easily overrides adrenergic activity in the eye, however, and responses to adrenergic drugs may vary considerably. The nictitating membrane, or third eyelid, is contracted by norepinephrine and epinephrine; conjunctival and scleral blood vessels are constricted. Intraocular pressure may decrease slightly upon local instillation of epinephrine; this effect is sometimes useful in treating wide angle glaucoma.

CENTRAL NERVOUS SYSTEM EFFECTS. Catecholamines do not readily cross the blood-brain barrier. Therefore, epinephrine and norepinephrine have little effect on the central nervous system (CNS). Certain noncatecholamine adrenergic agents, like amphetamine, readily cross the blood-brain barrier and elicit pronounced stimulation of the CNS.

METABOLIC EFFECTS. Catecholamines exert several rather striking effects on anabolic and catabolic activities in different organs and tissues. In mammals, there is an overall calorogenic effect (increase in general metabolism) associated with a 20-30% increase in oxygen consumption. Glycogenolysis occurs in the liver and skeletal and cardiac muscles following exposure to epinephrine, norepinephrine, or isoproterenol. There is also an acceleration of fatty acid mobilization and lactic acid formation. Accordingly, concentrations in the blood of glucose, free fatty acids, and lactic acid are increased. The order of potency of catecholamines in eliciting these metabolic changes varies in different tissues and species. In general, the glycogenolysis effect in muscles and liver follows the potency order of that associated with β receptors.

The metabolic activities of catecholamines have been associated with alterations of tissue concentration of cAMP. In hepatic and muscle tissue, e.g., adenylyl cyclase activity is increased by catecholamines, resulting in an accelerated conversion of ATP to cAMP, which in turn activates protein kinase A; the latter accelerates conversion of the inactive phosphorylase enzyme (phosphorylase b) to an active form (phosphorylase a) that then catalyzes the catabolism of glycogen to glucose. Similarly, the catecholamines have been associated with changes in the relative activities of other protein kinases, lipases, and phosphofructokinases by increases in cAMP formation.

ABSORPTION AND BIOTRANSFORMATION. Epinephrine and norepinephrine are not absorbed to any appreciable extent following oral administration because of destruction within the GI tract. The liver rapidly inactivates by oxidative deamination and conjugation any norepinephrine or epinephrine that is absorbed into the portal system. Isoproterenol is absorbed following oral or sublingual administration but often in such an erratic manner as to be therapeutically nonuseful. Catecholamines are readily absorbed from aerosolized sprays or after parenteral administration. Subcutaneous (SC) dosages are more slowly absorbed than intramuscular (IM) injections.

Injected norepinephrine and epinephrine are metabolized by MAO and COMT (catechol-*O*-methyltransferase) enzymes; the inactive metabolites are excreted in urine. A portion of the *O*-methylated and deaminated metabolites are conjugated prior to excretion. MAO and COMT are present in many tissues; breakdown of catecholamines does not depend entirely upon the liver or kidney. Uptake of norepinephrine and epinephrine into adrenergic neurons away from their active receptor sites is an important pathway for termination of their pharmacologic activities (see Chap. 5). This is demonstrated by injecting a drug that blocks the amine uptake pump, e.g., cocaine, which potentiates the pressor response to norepinephrine and epinephrine. Inhibition of MAO and COMT has little effect on responses to single injections of catecholamines.

PREPARATIONS. *Epinephrine*, USP, the free base, is obtained from adrenal medullary extracts of domestic farm animals or is chemically synthesized. It is a white or light brown crystalline powder that is relatively insoluble in water but readily forms the water-soluble salt epinephrine hydrochloride upon addition to dilute hydrochloric acid. Solutions are unstable in alkaline mediums or upon exposure to light or heat and discolor to pink and eventually brown. Discoloration indicates oxidation of epinephrine to an inactive form; such solutions should be discarded.

Epinephrine Injection, USP, and *Epinephrine Solution*, USP, are aqueous solutions of epinephrine hydrochloride (adrenaline hydrochloride) prepared in a 1:1000 (1 mg/mL; 0.1%) solution; they are probably the most commonly used preparations of epinephrine. The former solution is sterile. Addition of small amounts of sodium bisulfite retards oxidative breakdown of epinephrine.

Sterile Epinephrine Suspension, USP, is a sterile suspension of epinephrine, usually 2 mg/mL, in sesame or peanut oil for IM injection only. This product is used when prolonged activity is desired.

Epinephrine Bitartrate, USP, is available in aerosol and ophthalmic solutions.

Norepinephrine (levarterenol) Bitartrate, USP (*l*-norepinephrine bitartrate), is a white crystalline powder (monohydrate salt) that readily dissolves in water. Solutions turn pink upon exposure to light, heat, or air and should be discarded if discoloration occurs.

Norepinephrine (levarterenol) Bitartrate Injection, USP, is a sterile aqueous solution usually containing 0.2% (2 mg/mL) of the salt (equivalent to 0.1% or 1 mg/mL of norepinephrine base). Bisulfite is included to delay oxidation.

Isoproterenol Hydrochloride, USP (Isuprel hydrochloride), is the water-soluble hydrochloride salt. Solutions of this compound also oxidize when exposed to light or air.

Isoproterenol Hydrochloride Injection, USP, is a sterile aqueous solution of isoproterenol hydrochloride for parenteral injection. Available preparations usually contain 0.2 mg/mL (0.02%).

Isoproterenol Hydrochloride Tablets, USP, are available in 10 mg and 15 mg sizes.

CLINICAL USE

WITH LOCAL ANESTHETICS. Epinephrine is commonly used in concentrations of 1:100,000 to 1:20,000 in local anesthetic solutions. It causes pronounced local vasoconstriction and thereby localizes the action and delays the absorption of the infilterable anesthetic. Since norepinephrine is a less potent α agonist than epinephrine, it is infrequently used in local anesthetic solutions.

LOCAL HEMOSTATIC. Vasoconstrictor effects of epinephrine (1:100,000 to 1:20,000 solution) may be used to control superficial bleeding of mucosal and SC surfaces by application of moistened gauze sponges or by aerosol sprayed directly onto the damaged region. Epinephrine solutions have been used topically during ophthalmic surgery to control hemorrhage. Epistaxis and dental extractions are other indications. Epinephrine is effective only against hemorrhage from capillaries and arterioles and should not be used in attempts to control bleeding from larger vessels. Although smooth muscle of large vessels contracts in response to amines, this effect is by no means sufficient to occlude the lumen. During surgery, topical application of epinephrine should be considered only as a temporary aid for controlling bleeding to assist in visualization of the operative field. Serious bleeding may well recur subsequent to termination of activity of this catecholamine if routine ligation of blood vessels is disregarded.

HYPOTENSION. Pressor amines are often used to maintain blood pressure during spinal surgery, and epinephrine is quite effective in treating hypotension associated with anaphylactic shock. The peripheral vasoconstrictor effects of norepinephrine, epinephrine, and other adrenergic drugs have also been used in attempts to treat and prevent hypotension occurring during other shock syndromes. However, blood pressure elevation due to peripheral vasoconstriction is not an adequate substitution for correcting serious underlying problems such as hypovolemia, undetected hemorrhage, and electrolyte and fluid imbalances. Some shock states are characterized by peripheral vasoconstriction secondary to a generalized sympathoadrenal discharge. Under such circumstances, administration of epinephrine or norepinephrine may serve to compound the problem by causing further intensification of vasoconstriction in vital areas (e.g., splanchnic and renal vascular beds) (Adams and Parker 1979). In some cases, the exact opposite effect (blockade of α-adrenergic receptors) has been proposed as a treatment in shock. These factors should always be considered when use of sympathomimetic amines during shock therapy is considered.

In shock cases characterized by loss of vascular tone, use of pressor amines has been suggested. Also, reestablishment of normal blood volume in some shock patients does not seem to correct the vascular complications, and blood pressure remains seriously depressed. Pressor agents may be of some use. Norepinephrine has been used under these circumstances. Usually, a 4 mL vial of 0.2% norepinephrine bitartrate (0.1% of free norepinephrine base; 1 mg/mL) is added to 1 L of sterile isotonic saline solution or 5% dextrose solution, which gives a final concentration of norepinephrine base of 4 μg/mL of solution. This solution is slowly infused intravenously until blood pressure is maintained somewhat lower than normal. Usually, an infusion rate of 0.1-0.2 μg/kg/min proves effective; however, administration should be to effect. The pressor response to norepinephrine can be readily controlled since it disappears within 1 or 2 minutes after stopping the infusion. Blood pressure should be closely monitored during the infusion process. An attempt should always be made to closely monitor cardiovascular function during treatment with any of the catecholamines. Isoproterenol has been used in some low cardiac output stages of shock. Soma et al. (1974) recommend a slow IV infusion of a 0.1-0.2 μg/mL solution of isoproterenol.

CARDIAC EFFECTS. Catecholamines are indicated in treatment of certain cardiac disorders: cardiac arrest, partial or complete atrioventricular (AV) block, and Stokes-Adams syndrome (Adams 1981). With cardiac arrest, an attempt is first made to restore heartbeat by mechanical means such as a precordial blow, electrical shock, or external cardiac massage. If the heart starts contracting, isoproterenol or epinephrine can be given by slow IV drip to maintain heart rate and cardiac output after circulation is restored. Care should be taken with IV infusion, since epinephrine may precipitate ventricular fibrillation if prefibrillatory rhythm is presented.

If asystole persists, norepinephrine, epinephrine (0.5-1.0 mL of a 1:10,000 solution; i.e., 50-100 μg), or isoproterenol (20-40 μg) may be administered directly into the left ventricular chamber in an attempt to restore contraction. Larger doses may be required in some instances. The heart should then be massaged to ensure circulation of the catecholamine through the coronary vasculature. Peripheral circulation should be maintained by cardiac massage until myocardial contraction is restored.

Isoproterenol is used for treating heart block. Complete AV heart block in a dog was treated with 0.05 mg (approximately 3.5 μg/kg) of isoproterenol administered intravenously; the heart rate increased almost immediately from 44 beats/minute to 68 beats/minute (Buchanan et al. 1968). Because of its potency, isoproterenol should be administered by slow IV infusion rather than rapid bolus injection. Slow IV drip of a diluate solution can be instituted until the heart rate is maintained at 80-100 beats/minute. Thereafter, IM injections of 0.1-0.2 mg isoproterenol every 4 hours may prove effective. Isoproterenol tablets (15-30 mg) have been given every 4 hours; however, patients should be closely monitored because absorption after oral administration is erratic. Buchanan et al. (1968) found that orally administered isoproterenol (30 mg twice daily) was ineffective in treating complete AV block in a dog. Ettinger (1969) infused isoproterenol (5 μg/mL in dextrose and water) intravenously at a rate (usually 1 mL/minute) sufficient to maintain the ventricular rate at 80/minute. Isoproterenol was then administered subcutaneously every 6 hours at the dose of 0.2 mg. Oral administration of an isoproterenol tablet (30 mg) every 6 hours was prescribed for several weeks. Catecholamines should not be used in the presence of acute or chronic heart failure. These agents decrease efficiency of myocardial contraction by increasing oxygen demands of the heart muscle and compound the heart failure syndrome.

ANAPHYLACTIC AND ALLERGIC REACTIONS. Epinephrine is extremely effective and often lifesaving in treatment of acute anaphylactic shock. It quickly reverses the precipitous fall in blood pressure and cardiac irregularities associated with this type of syndrome. Histamine-like constriction of bronchiolar smooth muscles occurs during anaphylaxis; these effects are rapidly antagonized by epinephrine. Bronchiolar passageways are dilated by epinephrine as a result of relaxation of the smooth muscle, and dyspnea is quickly counteracted. Care should be taken that allergic signs do not recur after epinephrine activity has terminated.

BRONCHIAL ASTHMA. Isoproterenol and epinephrine have been useful for providing immediate relief from bronchial asthma. These agents activate the β_2 receptors of the bronchial smooth muscle cells, causing relaxation and prompt relief by dilating the airways. Norepinephrine is ineffective in dilating passageways even though it may transiently decrease mucosal congestion by constricting mucosal blood vessels. For systemic relief from allergic and anaphylactoid reactions, epinephrine can be administered subcutaneously or intramuscularly, because with these routes effective blood levels are quickly achieved. However, if a patient is presented in late stages of anaphylactic shock or other similar life-threatening situations, IV administration may be required.

In large domestic animals (cattle, horses) 4-8 mg epinephrine can be given intramuscularly or subcutaneously by injection of 4-8 mL of a 1:1000 dilution of epinephrine solution. Sheep and swine may be administered 1-3 mL of the 1:1000 dilution. Dogs and cats are usually given 1-5 mL of a 1:10,000 (0.1 mg/mL) dilution. Based on a body weight range of approximately 5-25 kg, this represents a dosage schedule of approximately 20 μg/kg. A dose this large should be administered only by IM or SC injection. Response of animals to adrenergic drugs may vary considerably; therefore, repeat injections or somewhat larger doses may be required in some cases. If IV administration is necessary, one should proceed cautiously and give no more than 0.25-0.5 μg/kg. In experimental animals, 1-2 μg/kg epinephrine or norepinephrine administered by IV bolus injection causes a pronounced increase in cardiovascular activity, and even slightly larger doses may well lead to serious arrhythmias. Selective β_2 agonists (e.g., terbutaline, metaproteronol) may supplant epinephrine and isoproterenol as bronchodilators (see β_2-selective bronchodilators).

TOXICITY. As implied in the preceding discussion, toxicity of the catecholamines is usually characterized by untoward cardiovascular responses. In particular, cardiac dysrhythmias such as tachycardia and even fatal ventricular fibrillation may occur following inadvertent overdosage. Hyperthyroid conditions, thyroid therapy, digitalis therapy, halogenated hydrocarbon anesthetics, and thiobarbiturates predispose a patient to the myocardial toxicity of catecholamines. The influence of anesthetics on the arrhythmogenicity of catecholamines is believed to be due to sensitization of the heart muscle. Myocardial sensitization to catecholamines is evoked by trichlorethylene, ethyl chloride, cyclopropane, halothane, chloroform, methoxyflurane, and fluroxene (listed in order of decreasing effect) (Katz and Katz 1966). Thiobarbiturates increase the incidence of epinephrine- and norepinephrine-induced arrhythmias in chloroform-anesthetized dogs (Claborn and Szabuniewicz 1973; Wiersig et al. 1974).

Hypertensive crises occur from norepinephrine or epinephrine overdosage; cerebral vascular accidents and ruptured aneurysms may result. The latter represents a potential problem in horses because of a fairly common incidence of undiagnosed verminous aneurysms. Large or repeated dosages of epinephrine and isoproterenol have been associated with myocardial ischemia and necrosis; these effects are prevented by β-blocking agents. Local necrosis and sloughing of tissue may occur at injection sites because of intensive vasoconstriction and resulting ischemia.

In short, the catecholamines are extremely potent agents; under no circumstances should they be considered innocuous. Therapeutic use of these drugs should always be carefully monitored by a trained individual familiar with their indications, limitations, and toxicities.

Dopamine. Dopamine (3,4-dihydroxyphenylethylamine) was thought to be important only as the immediate precursor to norepinephrine. Dopamine itself is now known to have important physiologic functions in mammalian species and is receiving attention in certain clinical circumstances in humans (Caccavelli et al. 1992). Parkinson's disease, e.g., has been related to decreased concentrations of dopamine in the basal ganglia, and treatment with *l*-dopa has proved effective in controlling motor disorders in some Parkinsonism patients. *l*-Dopa crosses the blood-brain barrier (dopamine does not in significant quantities) and is decarboxylated to dopamine.

Experimental hemodynamic studies indicate that dopamine also has use as a selective cardiovascular agent. In anesthetized dogs, IV injection of 1-9 μg/kg dopamine induces a slight depressor response associated with a decrease in total peripheral resistance, a decrease in renal vascular resistance, an increase in renal blood flow, and an increase in cardiac output. Large amounts, 9-81 μg/kg, produce pressor responses and a more pronounced increase in myocardial contractile force (Setler et al. 1975). Cardiovascular effects of dopamine depend on activation of different types of catecholaminergic receptors. The pressor response is blocked by an α blocker (e.g., phenoxybenzamine), and the cardiac stimulatory effects are blocked by a β blocker (e.g., propranolol). Part of the myocardial effects of dopamine are thought to be indirect and mediated by release of norepinephrine from cardiac sympathetic nerves (Fig. 6.5).

The depressor effects of dopamine are not blocked by a β blocker but are blocked by haloperidol. Because the latter drug is a dopamine antagonist in the brain, it has been proposed that there are specific dopamine receptors in certain vascular beds (Goldberg and Rajfer 1985). The dopamine-responsive or dopaminergic receptors of vascular beds can be considered a fifth adrenergic receptor subtype. Although the physiologic purpose of the vascular dopamine receptors is unknown, this receptor type is important to clinical pharmacology because it subserves vasodilatory responses in the renal, visceral, coronary, and cerebral

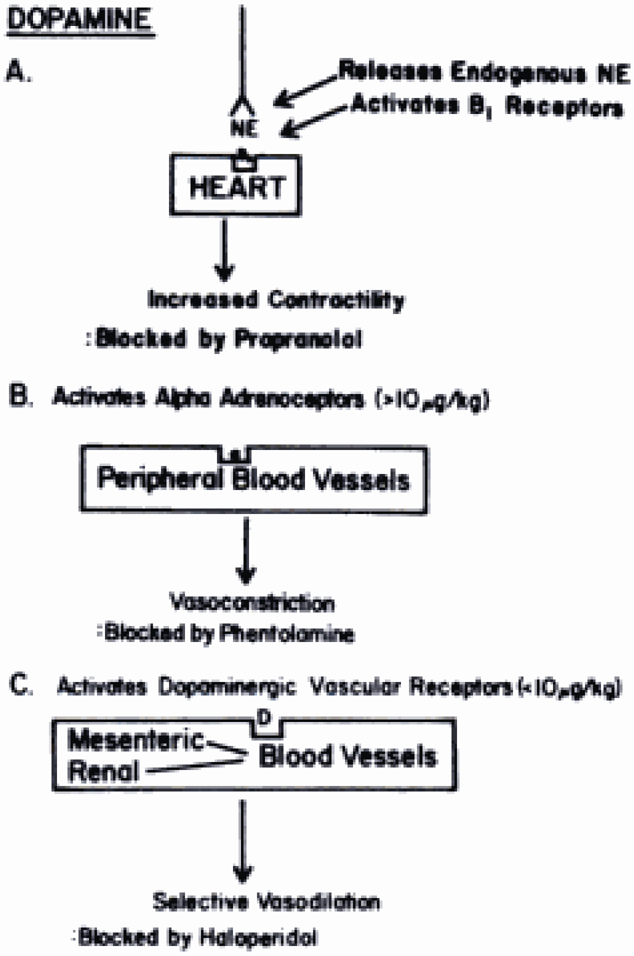

FIG. 6.5—Cardiovascular activities of dopamine. (A) Dopamine increases heart rate and myocardial contractility by directly activating β_1 adrenoceptors and releasing neuronal stores of endogenous norepinephrine (NE); these activities are blocked by the β-blocking agent propranolol. (B) Dopamine in large doses activates α adrenoceptors of blood vessels, resulting in vasoconstriction and a pressor response. This is blocked by the α-blocking agent phentolamine. (C) Dopamine in low doses can selectively dilate mesenteric and renal arterial beds (and perhaps cerebral and coronary arterial beds) by activation of dopamine-response (dopaminergic) receptors. It is not blocked by an α- or β-blocking agent but is blocked by the CNS dopamine antagonist haloperidol (Adams and Parker 1979).

beds. Dopamine activates these receptors rather selectively, whereas other catecholamines have unimportant agonist activity at these sites.

Dopamine causes decreased vascular resistance and increased blood flow to the kidneys and mesenteric circulation concurrent with myocardial stimulation. This particular aspect may be an advantage over conventional catecholamines in treatment of shock, because norepinephrine and epinephrine markedly constrict renal and mesenteric arteries as a result of α-receptor effects, and because isoproterenol has little effect on resistance in these regions owing to a relative lack of β-vascular receptors in these tissues (Adams and Parker 1979).

Selective vasodilation of renal and splanchnic beds by dopamine has prompted use of this agent in clinical cases of cardiovascular dysfunction. The optimal dose range of dopamine for selective vasodilation and cardiac stimulation in dogs is about 1-10 µg/kg/min administered by IV infusion; higher doses run the risk of α-vasoconstrictor effects owing to loss of dose-dependent dopamine receptor selectivity (Fig. 6.5). One study indicated that dopamine (about 5 µg/kg/min) was effective in terminating advanced AV heart block in 4 ill foals that were refractory to atropine (Whilton and Trim 1985).

Dopamine receptors of vascular smooth muscle are categorized as dopamine$_1$ (DA$_1$), and the inhibitory dopamine receptors of peripheral sympathetic neurons are DA$_2$ subtype (Goldberg and Rajfer 1985). The relevance of this nomenclature to cardiovascular therapeutics in veterinary medicine remains to be established.

Dobutamine. Dobutamine hydrochloride (Dobutrex) is a synthetic catecholamine that evokes a positive inotropic response in the heart. Importantly, dobutamine elicits this activity via an activation of β_1 receptors subserving increased myocardial contractility, with less activity at β_1 receptors subserving chronotropic effects and β_2 receptors subserving peripheral vasodilation. This compound was formulated and synthesized by Tuttle and Mills (1975) in a search for agents that would selectively increase cardiac contractility without affecting heart rate, cardiac rhythmicity, or blood pressure. The net cardiovascular response to dobutamine actually comprises different effects of its sterioisomers as well as important reflex adjustments (Swanson et al. 1985).

Potential advantages of dobutamine over conventional catecholamines relates to the relative multiplicity of actions of the latter agents. Isoproterenol, for instance, is the most powerful inotropic catecholamine presently available; however, it usually produces this effect accompanied by excessive tachycardia, which substantially increases myocardial oxygen demands. The positive inotropic activity of norepinephrine is limited by peripheral vasoconstriction and, hence, increased afterload and cardiac workload. Also, the tachyarrhythmogenic potential for isoproterenol, norepinephrine, epinephrine, and even dopamine is an important consideration. Dobutamine, because of its relative inotropic cardioselectivity, may therefore have advantages over other adrenergic amines in the therapy of low-output cardiac failure.

The hemodynamics of dobutamine were studied in dogs by Hinds and Hawthorne (1975) and Willerson et al. (1976). Dobutamine produces a dose-related increase in myocardial contractility, velocity of myocardial fiber shortening, ejection fraction, and stroke work. Importantly, these increments in cardiac contractility occur without changes in ventricular preload or heart rate when dobutamine is infused in doses of 5-20 µg/kg/min; cardiac output increases and total peripheral resistance is slightly decreased. FIG. 6.6—Pathways of adrenoceptor activation by adrenergic drugs. Norepinephrine (NE) is stored in neuronal vesicles. Direct-acting adrenergic drugs activate the receptors of the effector cell; indirect-acting agents evoke release of endogenous NE. Arrows point to sites of action (Adams and Parker 1979).

cardiopulmonary bypass in dogs, mortality rate and cardiovascular function were improved by dobutamine infusion (5 µg/kg/min); an increase in automaticity or arrhythmia was not detected (Eyster et al. 1975).

In dogs anesthetized with pentobarbital, Willerson et al. (1976) found increased ST-segment elevation during infusion of dobutamine after coronary artery ligation; heart rate also increased under these conditions. Tachycardia, arrhythmia, and blood pressure changes are likely if optimal dosage levels are exceeded. More information is needed about the cardiac and hemodynamic actions of dobutamine, particularly in different species and under clinical conditions. However, dobutamine is an important adrenergic agent because of its relative inotropic cardioselectivity when the desired goal of therapy is to improve ventricular function by direct inotropic stimulation (Loeb et al. 1977).

NONCATECHOLAMINES. Although the 3,4-dihydroxybenzene structure yields maximum potency, many drugs lacking the catechol nucleus have proved to be clinically useful. As with the catecholamines, the end effects of these drugs are mediated by the adrenergic receptors of effector cells. However, the mechanism of obtaining receptor activation varies considerably from one drug to another. Surgical sympathetic denervation abolishes or markedly reduces the effects of some agents (e.g., tyramine, an experimental sympathomimetic amine) but does not reduce effects of epinephrine. Reserpine causes a functional sympathectomy by depleting adrenergic neurons of their stores of norepinephrine. Pretreatment with reserpine markedly decreases the response to tyramine but does not decrease effects of epinephrine. An α-blocking agent, however, prevents effects of tyramine, epinephrine, and norepinephrine. These findings indicate that tyramine acts presynaptically to cause a release of endogenous norepinephrine from the nerve, which in turn acts on postjunctional receptors. Based on these types of findings, adrenergic drugs can be classified into three groups: direct-acting (effects not decreased by denervation), mixed-action (effects partially reduced by denervation), and indirect-acting (effects markedly reduced by denervation) (Fig. 6.6).

Despite these complex interrelationships, the peripheral effects of adrenergic drugs can be explained by activation, whether direct or indirect, of the α and/or β receptors. Therefore, effects of these drugs can be compared with the previously discussed pharmacologic effects of the direct-acting agents norepinephrine, epinephrine, and isoproterenol.

Ephedrine. *Ephedrine*, USP, was originally isolated from the Chinese shrub *Ma huang (Ephedra)* but is now chemically synthesized. The natural product has been used in oriental medicine for centuries and was introduced into modern therapeutics during the 1920s (Chen and Schmidt 1930). The structure of ephedrine and related pharmacologic effects are shown in Table 6.1. The levo isomer is the most active form of this component. Ephedrine exerts its sympathomimetic effects by direct activation of adrenergic receptors and release of endogenous norepinephrine.

PHARMACOLOGIC EFFECTS

CARDIOVASCULAR. IV administration of ephedrine produces hemodynamic changes similar to those caused by bolus injection of epinephrine. Systolic and diastolic blood pressures increase, myocardial contractile force increases, heart rate increases if vagal reflexes are blocked, and cardiac output increases if venous return is adequate. Vasoconstriction occurs in kidney, mesenteric, and cutaneous circulations; blood flow to these regions decreases. Blood flow may increase, however, through coronary, cerebral, and skeletal muscle vascular beds. Ephedrine is many times less potent a pressor agent than epinephrine, but its effects last 7-10 times longer. Cardiovascular effects are obtained after oral administration of ephedrine, whereas epinephrine is inactive if given by mouth.

In contrast to epinephrine and norepinephrine, repeated injections of ephedrine evoke progressively smaller pressor responses in intact animals. This condition, tachyphylaxis, is probably dependent upon different factors. First, because ephedrine causes a release of endogenous amines, stores of norepinephrine may eventually be depleted, so less and less is available for release. The long duration of action of ephedrine may also contribute to development of tachyphylaxis. During long courses of cardiovascular stimulation, reflex mechanisms attempt to return hemodynamic function toward normal. Blood pressure may return to somewhat normal values, although ephedrine, because of its delayed elimination, is still present at receptor sites. Repeated injections therefore prove less effective if occupation of the receptors by prior administration of ephedrine still exists.

CENTRAL NERVOUS SYSTEM. Ephedrine is a CNS stimulant. It stimulates corticomedullary regions and, in large doses, causes excitement, apparent anxiety, and muscular tremors. Respiratory centers of the medulla oblongata are activated by appropriate doses of ephedrine. This effect has been used clinically to reverse respiratory depression, particularly if respiratory problems are associated with barbiturate overdosage. Ephedrine is infrequently used for this purpose now, since other central stimulants have proved more effective or more reliable. Other adrenergic drugs such as amphetamine stimulate the CNS to a greater extent than ephedrine.

OCULAR. Mydriasis occurs after local or systemic administration of ephedrine as a result of active stimulation of the radial muscle of the iris. A 10% solution has been used to enlarge the pupillary space to facilitate ophthalmic examination.

BRONCHIAL SMOOTH MUSCLE. Ephedrine is effective in causing relaxation of bronchial smooth muscle and increasing the diameter of bronchiolar passageways; these effects are believed to be due to direct activation of β receptors.

CLINICAL USE. *Ephedrine Hydrochloride,* USP, is used rarely in veterinary medicine. It offers no particular advantage over epinephrine except that its duration of action is longer and it is effective when given orally. Indications for use of an adrenergic drug in veterinary medicine usually require an immediate response, which can often best be obtained with injection of epinephrine.

The prolonged duration of the pressor effect of ephedrine may be of some benefit in maintaining blood pressure without having to resort to repeated injection or constant perfusion with a catecholamine. Use of 10-20 mg ephedrine administered by IV or IM injection has been advocated for pressor effects in dogs (Soma et al. 1974).

Ephedrine solution, 1-1.5%, can be applied topically onto congested mucosal membranes to evoke vasoconstriction and decongestion. Ephedrine is effective in reducing allergic responses, but the onset of action is slower than with epinephrine. Ephedrine is sometimes included in cough suppressant preparations for relief from bronchiolar congestion and vascular constriction.

Amphetamine. *Amphetamine Sulfate,* USP, or β-phenylisopropylamine, induces pronounced stimulation of the CNS as well as causing marked peripheral α and β effects. A considerable portion of the pharmacologic effects of amphetamine is due to release of endogenous norepinephrine. Cardiovascular effects of amphetamine are somewhat similar to those produced by ephedrine. An increase of systolic and diastolic blood pressures is observed. Heart rate is reflexly slowed and cardiac output is not affected to any appreciable extent. Cardiovascular effects are observed after the drug is given by the oral route. The *l*-isomer is a somewhat more active pressor agent than the *d*-isomer. The chemical structure of amphetamine is shown in Table 6.1.

Amphetamine is active if given by mouth; CNS effects persist for several hours. The entire CNS is affected, but effects on the cerebrum are most evident in humans: increased alertness, loss of fatigue, euphoria, and a sense of exhilaration. The performance of athletes is improved; this is attributed to improvement of activities requiring mental and physical coordination. After effects of amphetamine have dissipated, pronounced depression may occur. In humans amphetamine is most often used in treatment of neuropsychiatric disorders such as mild but chronic depression, narcolepsy, alcoholism, and in some cases of hyperkinesis in children.

Amphetamine is no longer available for use in veterinary medicine in the USA and is subject to strict control under the 1970 Controlled Substances Act. Prior to the strict control of amphetamine it was used in veterinary therapeutics for its stimulatory effects on the respiratory centers in the medulla oblongata. The entire cerebrospinal axis is affected, but particularly the brain stem and cortex. The *d*-isomer, dextro-amphetamine, is the most centrally active. Its analeptic potency is similar to that of pentamethylenetetrazol. Amphetamine increases both the rate and depth of inspiration in anesthetized animals. It was used intravenously (4-4.5

mg/kg) in the dog to overcome respiratory depressant effects of barbiturate overdose.

Phenylephrine. *Phenylephrine Hydrochloride,* USP (Neo-Synephrine), is similar in structure to epinephrine except that it lacks the 4-OH group on the benzene ring; the chemical structure and pharmacologic characteristics of phenylephrine are shown in Table 6.1. Phenylephrine is a direct-acting sympathomimetic amine at α_1 receptors and does not depend upon release of endogenous norepinephrine for its effects. Similar to norepinephrine, phenylephrine causes peripheral vasoconstriction by direct activation of α_1 receptors of blood vessels. However, dissimilar to norepinephrine, it has very little effect at cardiac β receptors. Systolic and diastolic blood pressures are increased by phenylephrine; reflex bradycardia usually occurs. The predictable reflex-mediated slowing of the heart rate by phenylephrine has led to use of this agent in human patients to control episodes of paroxysmal atrial tachycardia.

Phenylephrine is a less potent pressor agent than norepinephrine but has a longer duration of action. The IV dose for dogs is 0.088 mg/kg; approximately twice this amount should be given if administered by the SC or IM route.

Methoxamine and Metaraminol. The chemical structure of *Methoxamine Hydrochloride,* USP (Vasoxyl), is β-hydroxy-β-(2,5-dimethoxyphenyl)-isopropylamine. The chemical structure and related pharmacologic effects of *Metaraminol Bitartrate,* USP (Aramine), are included in Table 6.1. Like phenylephrine, these drugs act almost exclusively as direct-acting sympathomimetic amines at peripheral α receptors. They have minimal detectable myocardial stimulatory properties. Their pressor effects on systolic and diastolic blood pressures can be explained by peripheral vasoconstriction and increased peripheral resistance. Reflex bradycardia usually results. These drugs are used as pressor agents. After IV injection, the pressor response to methoxamine occurs rapidly and may persist for 1 hour. With IM administration, 15 minutes is usually required for the pressor response to take effect and it usually lasts 1-1.5 hours.

α_2-SELECTIVE AGONISTS. The CNS contains α_2 receptors on neurons involved in control of blood pressure and heart rate. CNS α_2 receptors also modulate CNS perception of pain as well as levels of sedation. Activation of CNS α_2 receptors by α_2 agonists can lower systemic blood pressure, explaining their role as antihypertensive agents in human medicine. In veterinary medicine, α_2 agonists are used for their sedative and analgesic properties, thereby gaining chemical restraint and relief from pain.

β_2-SELECTIVE BRONCHODILATORS. The β_2-agonist effects of isoproterenol have been used successfully to improve airway diameter and conductance in obstructive pulmonary disorders such as bronchitis, emphysema, and asthmatic-like syndromes. Because of equipotent β_1 activity, however, cardiac excitation and tachydysrhythmias represent limiting side effects of isoproterenol when only β_2-bronchodilator action is sought. Similar limitations apply to epinephrine, although it is still the drug of choice for treating acute anaphylaxis when a combination of β_2 bronchodilation, β_1-cardiac stimulation, and α vasoconstriction is needed. Cardiac side effects with epinephrine or isoproterenol can develop after any route of administration but are more pronounced after parenteral injection than with aerosol inhalation. For these reasons, considerable effort has been expended in the development of drugs with more selective β_2 activity and therefore less propensity for β_1-cardiac excitation.

Metaproterenol, isoetharine, terbutaline, salbutamol, pirbuterol, and clenbuterol are new drugs that meet the requirements for high β_2- and relatively less β_1-agonist activity. Indeed, these drugs are generally classified as β_2-selective bronchodilators. Most of these compounds are absorbed after oral administration and have prolonged duration of bronchodilator action, other distinct advantages over the short-lived response to isoproterenol and epinephrine.

Clenbuterol was shown to improve airway conductance in horses for several hours after a single IV injection at a dose of 0.8 μg/kg; heart rate increased dramatically but for less than 2 minutes (Shapland et al. 1981). The brief tachycardia may have been reflexly mediated due to transient β_2 vasodilation and hypotension. Unanticipated blood pressure responses may therefore represent a concern after systemic administration of β_2 bronchodilators. Blood pressure changes should be less pronounced after aerosol inhalation. However, untoward side effects, including β_1-cardiac stimulation, can be expected with any route of administration if optimal dosage ranges of the β_2 bronchodilators are exceeded.

Patients often become refractory to bronchodilator effects of adrenergic agonists during long-term therapy, and this is believed to reflect "down-regulation" or agonist-induced loss of the β_2-pulmonary receptor population. An alternative approach involves concomitant administration of a methylxanthine, such as aminophylline, along with the β_2 agonist. Methylxanthines inhibit the intracellular enzyme known as phosphodiesterase. This enzyme is responsible for the metabolism of cAMP, which is the intracellular messenger for β-receptor activation and mediates the resulting cellular reactions that culminate in bronchodilation. Because the results of β-receptor stimulation are mediated through an increase in cAMP synthesis and because methylxanthines inhibit the breakdown of cAMP and prolong its intracellular sojourn, combined therapy with a β_2 agonist and aminophylline can result in accentuated bronchodilator effects.

ANTIADRENERGIC DRUGS. Numerous agents have been discovered that prevent either the pharmacologic effects of sympathomimetic drugs, the physiologic responses evoked by stimulation of adrenergic nerves, or both. The terms adrenolytic and sympatholytic have been used to describe such activities; however, more precise terminology is presently in use. Adrenergic antagonists interact with adrenergic receptors and by occupying these sites do not allow an adrenergic agonist access to the receptor. Adrenergic neuron blocking drugs do not block receptors; instead, they act presynaptically at the nerve terminal to cause a decreased release of the endogenous neurotransmitter norepinephrine.

Adrenergic Antagonists. In 1906 Dale reported that pretreatment of cats with ergot alkaloids prevented some of the hemodynamic effects of epinephrine. These studies presented the first evidence of the drug action now commonly referred to as adrenergic blockade. Adrenergic blocking drugs exert their pharmacologic effects by interlocking with and occupying adrenergic receptors. In this manner, adrenergic agonists are prevented from affixing to the receptor site; effects of the agonist are abolished or markedly decreased.

The adrenergic blocking effects of ergot alkaloids (and some drugs like phentolamine that were subsequently synthesized) were identified as being present only at those adrenergic receptors designated by Ahlquist (1948) as α. In fact, for over 50 years the only adrenergic blocking agents identified inhibited α-receptor-mediated effects. This problem delayed full acceptance of Ahlquist's (1948) differentiation of α- and β-receptor sites. However, Powell and Slater (1958) and Moran and Perkins (1958) demonstrated that the 3,4-dichlorophenyl analog of isoproterenol selectively inhibited those responses ascribed by Ahlquist (1948) to be mediated by β receptors. This drug, dichloroisoproterenol, blocked the vasodilation, cardiac stimulation, and bronchial smooth muscle relaxing effects of catecholamines but had no effect on α-mediated effects. *Propranolol Hydrochloride,* USP (Inderal), was subsequently identified as a β-blocking agent, and it serves as the prototype for this drug group.

Pharmacologic Considerations

RECEPTOR BLOCKADE. The α- or β-inhibitory effects of representative adrenergic blocking drugs (e.g., α blockade with phentolamine and β blockade with propranolol) on the blood pressure and myocardial effects of sympathomimetic drugs are shown in Fig. 6.7. Alpha blockade abolishes the pressor response to norepinephrine. Epinephrine is a mixed α-β agonist; α blockade by phentolamine not only prevents the pressor response to epinephrine, it actually converts it to a depressor response. This is called epinephrine reversal. Since the α receptors are occupied by phentolamine, only the vasodilator β_2 receptors are available for interaction with epinephrine. Thus epinephrine causes a fall in blood pressure. Alpha blockade does not affect the β_2-receptor-mediated depressor effect of isoproterenol nor does it affect the cardiac stimulant effects of the catecholamines.

Propranolol, a nonselective β_1-β_2 blocker, inhibits the β_1-cardiac stimulant effects of isoproterenol, epinephrine, and norepinephrine (Fig. 6.7). It also blocks the β_2-depressor response to isoproterenol but does not prevent the α-receptor-mediated pressor response to norepinephrine. The secondary depressor effect of epinephrine seen in the control situation is due to residual β_2-receptor-mediated vasodilation; this too is inhibited by propranolol.

PHARMACOLOGIC EFFECTS. The degree of autonomic nervous system activity at any one time plays an important role in determining the extent of pharmacologic effects that will be produced by an adrenergic blocking agent. For example, administration of a β-blocking drug to a trained quiescent patient does not cause profound cardiovascular effects because at rest the heart is not under pronounced sympathetic influence. Upon physical exertion, however, an increase in heart rate and cardiac output is produced as a result of increased sympathetic nervous system activity. If the patient is required to exercise during treatment with propranolol, these characteristic cardiac responses are not obtained since the β-adrenergic receptors of the heart are blocked by this drug.

Effects of an α-blocking agent are similarly influenced by the existing state of autonomic nervous system activity. If the cardiovascular system is under pronounced sympathetic dominance (e.g., during fright or severe hypovolemia), an α-blocking drug will cause a decrease in blood pressure. This occurs because the α receptors of blood vessels are occupied by the α-blocking agent and are no longer available to norepinephrine or to circulating epinephrine.

Pharmacologic effects of adrenergic blocking agents can be reliably predicted by considering the distribution of α and β receptors in the body and the respective physiologic functions they subserve. Distribution of α and β receptors in various organs and tissues and their pharmacologic characteristics are summarized in Tables 5.1 and 6.3.

α-ADRENERGIC BLOCKING AGENTS

ERGOT ALKALOIDS. Ergot alkaloids are not used clinically in humans or lower animals for α-blocking effects. They affect a variety of organs at concentrations less than those required for α blockade. Therefore, they are not truly prototypical α blockers; however, they were the first adrenergic blocking agents identified (Dale 1906).

Ergot is a fungus *(Claviceps purpurea)* that parasitizes rye and other grains. Ingestion of contaminated grain products has caused outbreaks of ergotism in humans and domestic animals throughout the world. Ergot is a mixture of different types of alkaloids that

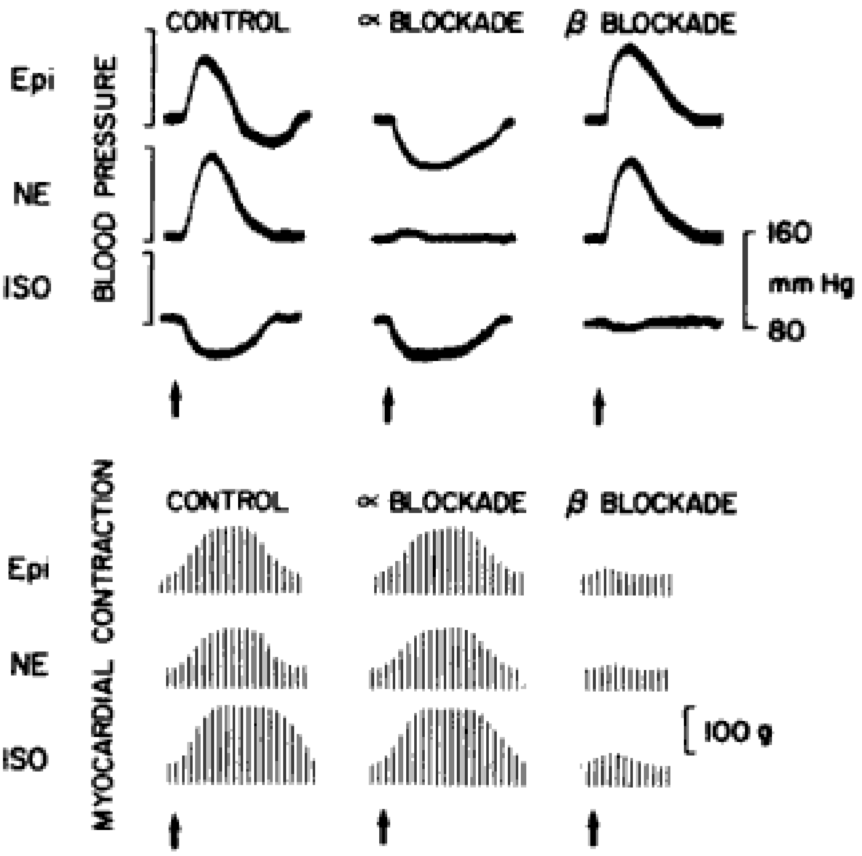

FIG. 6.7—Effects of α- and β-adrenergic blockade on the blood pressure and myocardial effects of epinephrine (Epi), norepinephrine (NE), and isoproterenol (ISO) in a dog. Control = effects of amines in the absence of an adrenergic blocking drug. α blockade = effects of amines after administration of an α blocker (e.g., phentolamine); β blockade = effects of amines after administration of a β blocker (e.g., propranolol). Epi, NE, or ISO was injected intravenously at arrow. α blockade inhibits the pressor response to NE, does not affect the depressor effect of ISO, converts the pressor effect of Epi to a depressor effect (Epi reversal), and does not affect the cardiac stimulant effects of the amines. β blockade does not affect pressor responses to NE, inhibits depressor effect of ISO, inhibits the secondary depressor effect of Epi, and inhibits myocardial stimulant effects of all three amines (see text for details).

TABLE 6.3—Classification and characteristics of catecholaminergic receptors

	Receptor types			
Characteristics	α	β_1	β_2	Dopamine
Potency of agonists	E > NE > D > I	I > E ≥ NE > D	I > E > NE > D	D > E, NE, I
Antagonists				
α blockers (PHEN)	Block	No	No	No
β blockers				
General (PROP)	No	Block	Block	No
β_1 (PRACT)	No	Block	Weak block	No
β_1 (BUT)	No	Weak block	Block	No
Dopamine antagonist (HAL)	No	No	No	Block

Note: E = epinephrine; NE = norepinephrine; D = dopamine; I = isoproterenol; PHEN = phentolamine; No = no blocking effect; PROP = propranolol; PRACT = practolol; BUT = butoxamine; HAL = haloperidol. See Table 6.4 for further breakdown of α receptors into α_1 – α_2 subtypes.

have biologic effects. The ergonovine group lacks a polypeptide side chain; it does not cause adrenergic blockade but has potent oxytocic activity. The ergotamine group causes adrenergic blockade but has little effect on nonvascular smooth muscle.

The predominant vascular effect of ergot is not α blockade but is related to intense peripheral vasoconstriction. These compounds cause a direct stimulation of smooth muscle, including that of peripheral blood vessels. Because of peripheral vasoconstriction, ergot initially causes a pressor response that may persist for a fairly long time. Larger doses eventually block the α-adrenergic receptors; α-receptor-mediated effects of norepinephrine, epinephrine, and

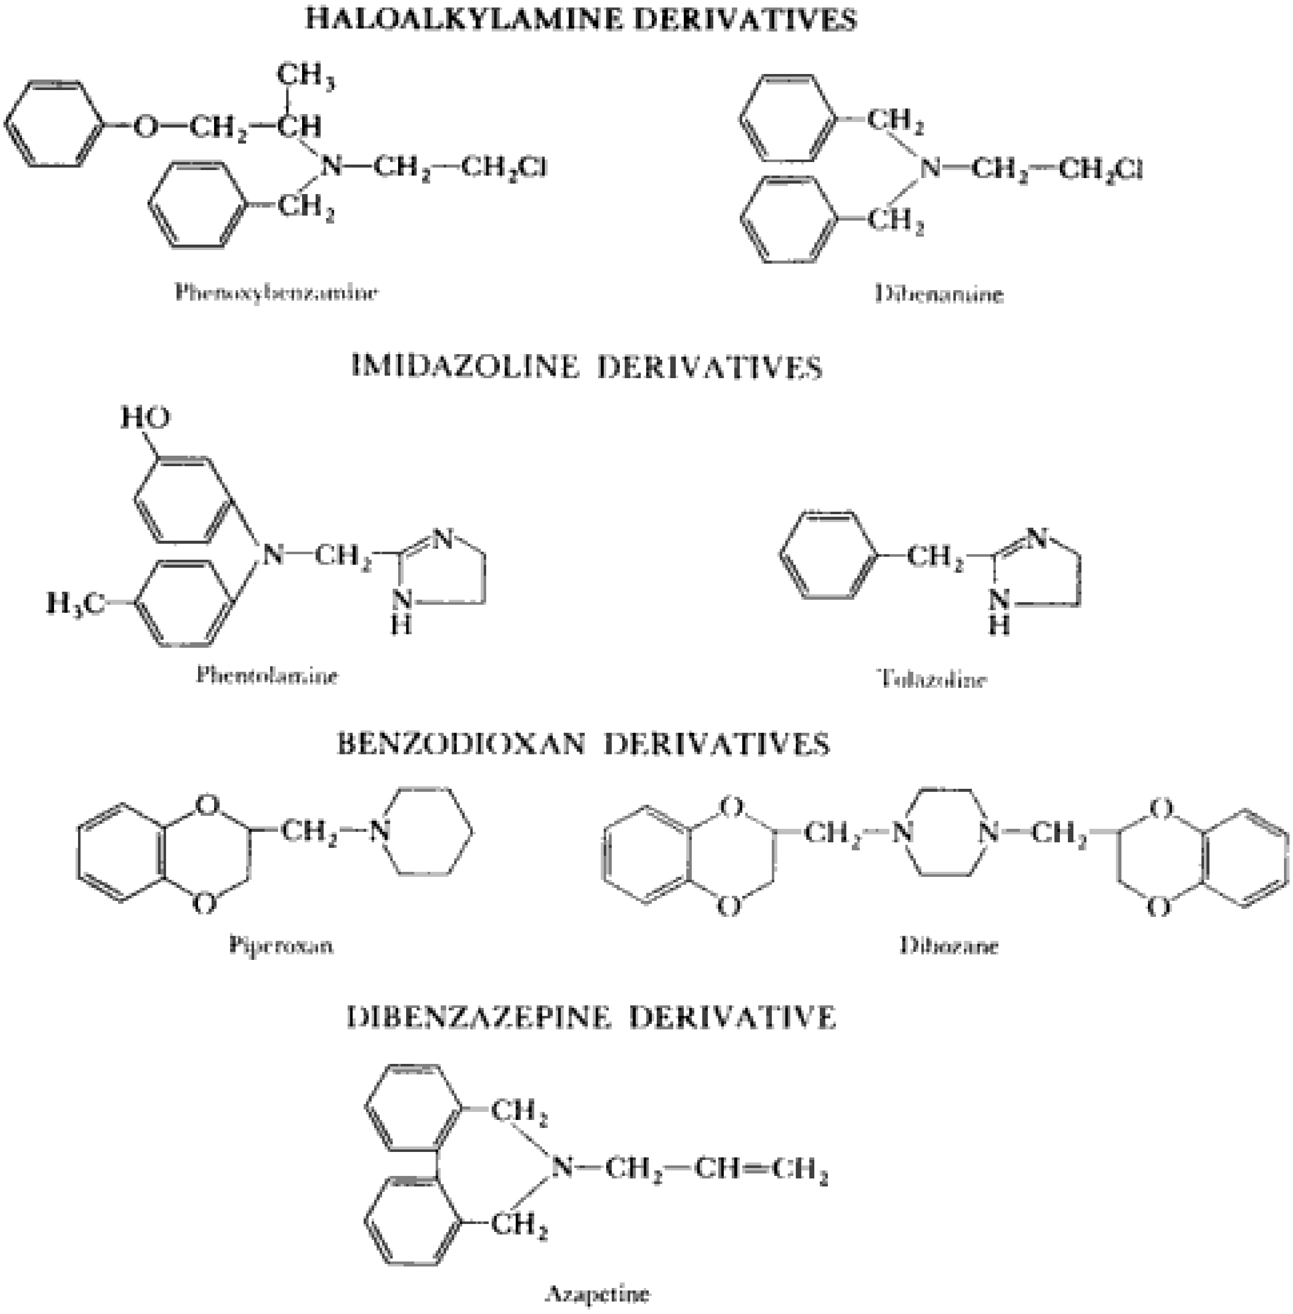

FIG. 6.8—Chemical structures of some α-adrenergic blocking drugs.

other agonists are inhibited. Beta receptors are not affected.

Because of α-blocking effects, ergot produces epinephrine reversal as previously described (Fig. 6.7). In ergot-treated animals, vasodilation and hypotension occur after administration of epinephrine (or other mixed α-β agonists) resulting from β-receptor dominance in the presence of α blockade. Although this is not the most prominent effect of ergot, it is the most interesting, since it led to identification of other, more selective α blockers. Large doses of ergot cause serious circulatory disturbances because of intense and persistent vasoconstriction of peripheral vessels. This is characterized by stasis of blood in the capillaries and arterioles, thrombosis, and eventually obliterative endarteritis, leading to gangrene of the extremities. Sloughing of portions of the feet, hooves, tails, ears, and tongues have occurred in ergot-poisoned animals.

SYNTHETIC α-BLOCKING AGENTS. The synthetic α blockers fall into several classes of structurally unrelated chemical compounds; structure-activity relationships have not been clarified. There are several groups of α blockers such as the haloalkylamine derivatives (phenoxybenzamine, dibenamine), the imidazoline derivatives (phentolamine, tolazoline), the benzodioxans (piperoxan, dibozane), and the dibenzazepine derivatives (azapetine); see Fig. 6.8 for chemical structures.

Members of the phenothiazine derivative tranquilizers also have α-adrenergic blocking properties. These drugs are discussed in detail in relation to their CNS effects in a later chapter; their peripheral vascular actions are also of interest. Chlorpromazine and several other related compounds can cause blockade of α receptors. These agents alter pressor effects of catecholamines (they can cause epinephrine reversal) but it seems likely that the total cardiovascular effects are from a variety of factors such as concomitant antihistaminic, antiserotonergic, and anticholinergic effects.

Inhibition of pressor responses to catecholamines by the other synthetic α blockers, however, can be ascribed almost entirely to α-receptor blockade. Phentolamine and phenoxybenzamine are older α-blocking drugs. Their site of action is the α receptor; β responses are not blocked. *Phenoxybenzamine Hydrochloride*, USP (Dibenzyline), and other related haloalkylamines such as dibenamine produce a noncompetitive block; increasing the dosage of an α agonist will not overcome the α blockade produced by phenoxybenzamine. This characteristic seems to be due to the drug binding in a very stable manner to the receptor or nearby structures. *Phentolamine Hydrochloride*, USP (Regitine hydrochloride), and *Tolazoline Hydrochloride*, USP (Priscoline hydrochloride), however, cause a competitive blockade of α receptors that can usually be antagonized by increasing the availability of agonist.

Cardiovascular Effects. Slow IV infusion of phenoxybenzamine or phentolamine to a normal patient usually does not cause a remarkable change in blood pressure. Usually, a slight to moderate fall in pressure occurs; however, these drugs will cause a marked hypotensive response if a patient's cardiovascular system is under pronounced sympathetic tone. This is particularly evident during hypovolemia, since in this state sympathetic discharge increases to maintain adequate blood pressure in the presence of low circulating blood volume.

If phenoxybenzamine or other potent α blockers are given by rapid IV injection, severe hypotension and other adverse cardiovascular effects are seen; however, these effects probably involve factors other than α blockade.

In humans, α blockade evokes little change in blood pressure if the patient is supine, but pronounced hypotension occurs when the patient stands. This response is called postural or orthostatic hypotension. It is due to blockade of the vascular α receptors that are normally active in the efferent limb of reflex blood pressure pathways.

Other reflex changes are also altered. Reflex hypertension caused by anoxia is prevented by α blockade, as is the pressor response to occlusion of the carotid arteries (the bilateral carotid artery occlusion reflex depends upon increased sympathetic vasoconstrictor tone and increased release of epinephrine from the adrenal gland). Because of their occupation of α receptors, α-blocking agents prevent transmission of the nerve impulse to the α receptors of blood vessel cells and also block interaction of circulating epinephrine with α receptors. In this manner, reflex pressor responses are inhibited. Alpha-blocking agents increase blood flow through capillaries and arterioles as a result of α-receptor blockade and perhaps some direct relaxing effect on vascular smooth muscle.

Positive inotropic and chronotropic effects of catecholamines in heart muscle are not prevented by phentolamine or phenoxybenzamine. However, studies have shown that drugs having α-blocking effects decrease arrhythmias caused by catecholamines (Claborn and Szabuniewicz 1973; Wiersig et al. 1974; Benfry 1993). This has been demonstrated in nonanesthetized subjects and after sensitization of the myocardium by halogenated hydrocarbon anesthetics. It is not known if this is mediated entirely by α blockade. The haloalkylamines have a slight direct depressant effect on the heart that may be involved. Also, inhibition of the pressor effects of catecholamines (known to contribute to sensitization of the myocardium to arrhythmias) may also contribute (Katz and Katz 1966).

Under certain conditions, α-blocking agents partially decrease the inotropic effects of catecholamines in isolated heart muscle. This response varies from species to species, and in some cases it is demonstrable only during abnormally low temperatures. Although heart muscle contains α_1 receptors that increase myocardial contractility, the positive inotropic and chronotropic effects of catecholamines are predominately β-receptor-mediated events.

Other Effects. Phentolamine and phenoxybenzamine cause relaxation of the nictitating membrane (3rd eyelid); contractile responses caused by stimulation of sympathetic nerves or administration of an α agonist are blocked in this structure. The ocular effects of epinephrine and norepinephrine are inhibited by α blockers, as are pilomotor effects. The GI tract is variably influenced by α blockers, caused in part by the presence of β receptors in this system that also subserve relaxation.

Pharmacokinetics. The haloalkylamines and the imidazolines are effective whether administrated by mouth or injection. However, the former group is absorbed inefficiently after oral administration; only 20-30% of the drug is absorbed in active form from the GI tract. The onset of action of phenoxybenzamine and dibenamine is prolonged even after IV administration. These drugs may be converted to active intermediates, which then exert α-blocking effects. Their local irritating properties restrict their clinical use to oral or IV administration. Effective blood levels of tolazoline may not be obtained after oral administration, since it is slowly absorbed from the GI tract and is rapidly excreted by the kidneys. Phentolamine is less than 30% as active when given by mouth as when injected. Biotransformation pathways of the α-adrenergic blocking agents have not been clarified. Several of these drugs may localize in body adipose tissue because of their relatively high fat solubility.

Clinical Use. The α-receptor blocking drugs have been used with varying degrees of success in attempts to reduce vasoconstriction in the treatment of peripheral vasospasm, hypertension, pheochromocytoma, and visceral ischemia during circulatory shock syndromes. Early members of the α-antagonist group have not achieved appreciable cardiovascular application in veterinary practice and they have proved only slightly more useful in human medicine.

Certain types or stages of shock syndromes have been reported to respond favorably to an α-blocking agent. This is believed to be due to antagonism of catecholamine-induced peripheral vasoconstriction in vital visceral regions (e.g., renal and splanchnic circulation). Phenoxybenzamine (0.44-2.2 mg/kg diluted in 500 mL isotonic saline or glucose) administered by slow IV infusion has been suggested as a treatment procedure for preventing ischemia of the microcirculation during shock in animals. If hypotension occurs upon administration of an α-blocking agent during shock, adequate fluid replacement has not been achieved. It is essential that additional administration of blood or plasma expanders be instituted prior to continuing the infusion of the α-blocking agent. Currently, α-blocking agents are used infrequently, if at all, during the management of circulatory shock.

NONSELECTIVE α_1-α_2 BLOCKERS. An important limitation to therapy with the older α blockers such as phentolamine and phenoxybenzamine is their paradoxic sympathomimetic activity, especially in the heart. Administration of α blockers can result in cardiac excitation and increased plasma concentrations of epinephrine and norepinephrine (Saeed et al. 1982). Historically, these effects were attributed to a triphasic adjustment in autonomic nerve activity instigated reflexly by the hypotensive response to inhibition of α-vasoconstrictor tone. These three phases are increased sympathetic efferent traffic over the cardioaccelerator nerves, decreased vagal impulses to the sinoatrial pacemaker, and increased sympathetic firing to the adrenal medulla. Study indicates, however, that the cardiac response to α-blocking agents is even more complex than originally surmised and involves yet a fourth pathway that incorporates the α_2-adrenergic neuronal receptors.

It is now known that phenoxybenzamine and especially phentolamine can block both α_1-and α_2-receptor subtypes (Table 6.4). Thus these drugs not only inhibit the α receptors of the vascular smooth muscle cell but can likewise block the α_2 receptors of the noradrenergic nerve endings (Fig. 6.2). Since the prejunctional α_2-receptor subtype controls the previously discussed feedback inhibition of norepinephrine and epinephrine release mechanisms, α_2 blockade would thereby free the noradrenergic neuron and adrenal chromaffin cell from a resident suppressor system (Saeed et al. 1982).

Source: Adams 1984.

Note: α_1-blocking activity diminishes and α_2-blocking activity increases as the list is traversed from top to bottom. Drugs in the middle are nonselective blockers of both receptor subtypes.

An important consequence of such action would be an augmentation of the net quantity of catecholamines mobilized and released by reflex mechanisms. This sequence would not be manifested at either α_1- or α_2-vasoconstrictor receptors, owing to the original nonselective α-receptor blocking action of the drug. In the heart, however, the increased availability of catecholamines can explain the β_1-receptor stimulation and accentuated cardiac responses that can be associated with use of nonselective α antagonists.

SELECTIVE α_1 BLOCKERS. Prazosin is an α antagonist with selectivity for the α_1-receptor subtype (Table 6.4). Since it leaves the prejunctional α_2 receptors operational, prazosin should exert less reflex sympathomimetic response than would a nonselective α_1-α_2 antagonist. Confirming this theory is a study that compares the hemodynamic effects of prazosin and phentolamine in conscious dogs (Saeed et al. 1982). Both drugs induced equivalent reductions in peripheral vascular resistance and blood pressure. Phentolamine also evoked significant increases in heart rate, cardiac output, oxygen consumption, and plasma concentrations of norepinephrine and epinephrine. Prazosin did not elicit these sympathomimetic side effects despite equivalent reduction in systemic blood pressure. The differences between prazosin and phentolamine can be explained by the α_1-receptor selectivity of the former, leaving intact the α_2-autoinhibitory mechanisms for catecholamine release (Fig. 6.2).

In addition, since extrasynaptic α_2 receptors of vascular smooth muscle also remain unblocked during therapy with prazosin, these vasoconstrictor receptors are available to help maintain vasomotor tone in the resistance and capacitance beds. Thus orthostatic hypotension seems to be less of a problem with α_1-selective blockers such as prazosin than with nonselective α_1-α_2 blockers such as phentolamine.

Because of reduced frequency of reflex cardiac excitation and orthostatic hypotension, prazosin and other

α_1-selective antagonists have established an important niche in antihypertensive therapy in humans. These agents may also prove useful as peripheral vasodilators for reducing cardiac workload without reflex tachycardia in heart failure syndromes. Indeed, a study indicated that peripheral vasodilation with prazosin was effective in 4 dogs with congestive heart failure that were refractory to digoxin (Atwell 1979). However, digoxin was continued at reduced dosage in 3 of the dogs. It is unclear whether the beneficial responses in these patients were attributable to unloading of the heart by prazosin, to improvement in digoxin dosage management, or to both.

SELECTIVE α_2 BLOCKERS. Yohimbine and rauwolscine are experimental drugs that have prominent blocking actions at α_2 receptors with little or no activity at α_1 receptors. These drugs are used commonly to investigate α_2-receptor-dependent mechanisms in different tissues. Also, there is considerable interest in yohimbine as an antidote to CNS depressant drugs that have α_2-receptor agonist activity in the brain. Table 6.4 ranks the order of selectivity of several α blockers relative to their antagonistic activity at α_1- and α_2-receptor subtypes.

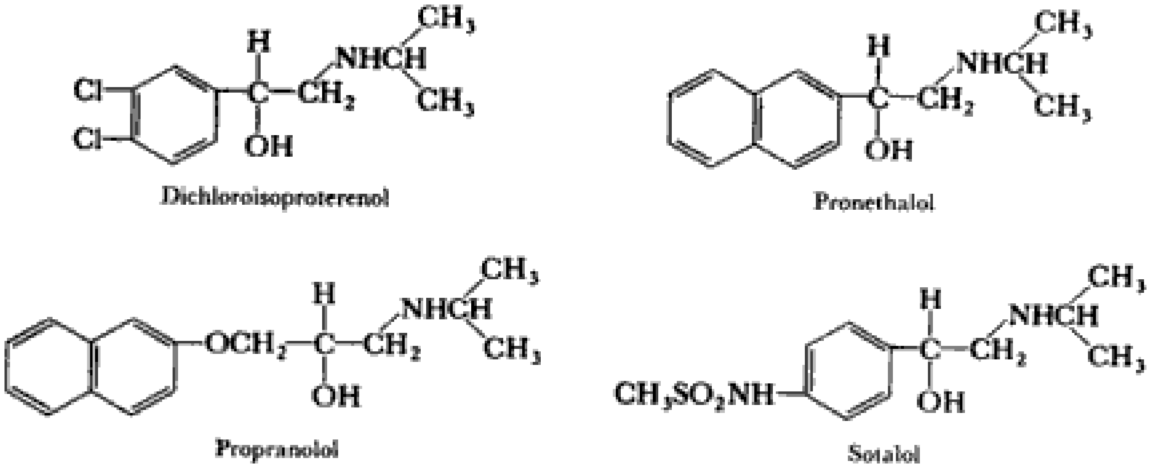
β-ADRENERGIC BLOCKING AGENTS. Dichloroisoproterenol was the first drug demonstrated to cause a specific blockade of β-adrenergic receptors. Because it also caused an initial stimulation of the same receptors, subsequent studies were directed to identification of other β-blocking agents that lacked agonistic properties. Propranolol is structurally related to its precursors; it is many times more potent than pronethalol and has very minimal agonistic effects. Propranolol and related β antagonists are somewhat similar in structure to the β agonist isoproterenol, as seen in Fig. 6.9. These compounds have an isopropyl-substituted secondary amine on the carbon side chain; this moiety appears to be important for effective interaction with the β receptor. The levoconfiguration of the asymmetric carbon atom on the side chain of propranolol yields the many times more potent β-blocking isomer than does the *d*-configuration.

CARDIOVASCULAR PHARMACOLOGIC EFFECTS. Propranolol causes minimal depression of heart rate, myocardial contractile force, and cardiac output during normal conditions, because at rest the heart is not under pronounced sympathetic tone. However, if the heart is functioning under sympathetic nervous system dominance (e.g., during exercise), a relative bradycardia and a rather pronounced decrease in myocardial contraction and cardiac output will be produced. This drug prevents the positive inotropic and chronotropic effects of catecholamines in the heart as a result of β_1-receptor blockade and antagonizes the arrhythmogenic actions of the catecholamines.

Under most physiologic conditions, β_2-vascular receptors participate only in a limited manner to homeostatic regulation. Thus β-blocking agents affect blood pressure primarily through their effects on cardiac output rather than by peripheral vascular effects. Vasodilation produced by isoproterenol or epinephrine is blocked by propranolol, however, and the vasoconstrictor response to epinephrine (α response) may be somewhat accentuated. The vasoconstrictor effects of norepinephrine or other α agonists are not blocked by propranolol.

Bronchiolar airways are under sympathetic dominance, resulting in an active state of relaxation of the bronchiolar smooth muscle. By blocking β_2 receptors, propranolol inhibits sympathetic bronchodilator activity and causes bronchiolar constriction. This effect is especially prominent during episodes of allergic reactions and bronchiolar asthma; nonselective β_1-β_2-blocking drugs are contraindicated in these and related conditions.

PHARMACOKINETICS. Effective blood concentrations of propranolol are obtained after oral administration,



Dichloroisoproterenol

Pronethalol

Propranolol

Sotalol

FIG. 6.9—Chemical structures of some β-adrenergic blocking drugs.

but a large dose is required when given by this route. Biotransformation takes place primarily within the liver, and several active metabolites have been identified. In some species, 4-hydroxypropranolol is as active a β-adrenergic blocking agent as the parent compound. Propranolol causes a competitive blockade of β receptors. Therefore, large doses of β agonists can overcome the β-blocking effects of this drug. Pharmacokinetic features of propranolol and other β blockers were reviewed by Muir and Sams (1984).

CLINICAL USE. In human medicine, the β-receptor antagonists are used rather extensively to help manage several important medical problems, including hypertension, angina, cardiac dysrhythmias, hypertrophic obstructive cardiomyopathies, hyperthyroidism, anxiety-related muscle tremors, glaucoma, and myocardial reinfarction. The β blockers are utilized considerably less in veterinary practice but have application for controlling cardiac dysrhythmias provoked by overactivity of the sympathetic nervous system. Controlled clinical trials are generally lacking; however, β blockers also have potential benefit in domestic animals for reducing cardiac work effort in obstructive cardiomyopathies and perhaps for lowering myocardial oxygen demand in chronic heart failure syndrome. By blocking the β_1 receptors of the heart, the drugs decrease the inotropic, chronotropic, and arrhythmogenic effects of the endogenous catecholamines and other β-adrenergic agonists.

Wiersig et al. (1974) reported that 1 mg/kg racemic propranolol administered intravenously to dogs markedly decreased the incidence of ventricular fibrillation induced by epinephrine and norepinephrine during halothane and thiobarbiturate anesthesia. In this respect, propranolol was more effective than chlorpromazine or acepromazine. Adrenergic antagonists should be infused very slowly when given by the IV route, since cardiovascular depression may occur if they are administered by bolus IV injection.

Beta-blocking drugs are frequently effective in decreasing AV conduction and thereby controlling ventricular rate in patients with atrial fibrillation or flutter. Propranolol has been shown to be effective in controlling atrial and ventricular arrhythmias induced by digitalis excess and in treating paroxysmal arrhythmias that prove resistant to digitalis and quinidine. In dogs, slow IV infusion of propranolol (1-3 mg) has been proposed for treatment of digitalis-induced supraventricular tachycardia, idiopathic sinus tachycardia, and supraventricular tachycardia. The oral dose is 10-40 mg every 8 hours.

β_1-SELECTIVE ANTAGONISTS. The preceding clinical uses of β antagonists depend on their block of the β_1-receptor subtype. Thus a drug with selective β_1-blocking action would have therapeutic capabilities equivalent to propranolol or other nonselective β_1-β_2 antagonists, but with reduced risk for loss of important β_2-receptor events as unwanted side effects. Propranolol and other β_1-β_2 blockers, e.g., are potentially harmful in certain patient populations owing to β_2-receptor inhibition in lung airways, leading to bronchoconstriction; in vascular smooth muscle, leading to changes in blood pressure and distribution of cardiac output; and in hepatocytes, leading to disruption of glucose metabolism. The latter condition is especially important in insulin-dependent diabetics, while loss of bronchodilator tone obviously is critical in patients with reduced respiratory reserve.

Some of the newly discovered β antagonists were found to be relatively more selective for the β_1- than for the β_2-receptor subtype. Metoprolol is protypical for this group. These drugs are commonly referred to as cardioselective β blockers because the mainstay of their clinical uses pertains to antagonism of the cardiac β_1 receptors. Some β blockers and associated affinities for receptor subtypes are included in Table 6.5, along with approximate biologic half-life values. Some of these compounds are lipophilic and undergo rather rapid biotransformation by liver enzymes, while others are lipophobic and depend upon renal excretory mechanisms for a longer half-life (Muir and Sams 1984).

β BLOCKERS AND REDUCED CARDIAC RESERVES. It should be remembered that β-blocking drugs, whether of the β_1-selective or β_1-β_2-nonselective group, should be administered cautiously in patients with preexisting heart disease. Under such conditions, cardiac performance may well depend on increased dominance of sympathetic activity as part of the compensatory attempt to maintain hemodynamics. Blockade of sympathetic input to the β_1 receptors of the heart, especially if sudden, can precipitate cardiac decompensation and failure. As a good example, Kittleson and Hamlin (1981) reported that propranolol caused cardiac decompensation in a dog with congestive heart failure that had been responding favorably to a vasodilator (hydralazine). If β blockade is attempted in the setting of reduced myocardial contractile reserves, it should be implemented cautiously with strict scrutiny of the patient's hemodynamic status.

INTRINSIC SYMPATHOMIMETIC ACTIVITY. An interesting facet of the pharmacodynamic profile of certain β blockers is their intrinsic sympathomimetic activity (ISA) (Table 6.5). This means that these agents exert partial agonist effects; hence, they maintain a slight basal stimulation of the β receptors while also preventing further receptor activation through their primary antagonistic action. An advantage of ISA might be that basal tone to the cardiac β_1 receptors and pulmonary β_2 receptors may forestall cardiac depression and bronchoconstriction respectively. Another advantage of low-grade β-receptor stimulation might be a reduced tendency for the up-regulation of β-receptor numbers that can follow long-term therapy with β antagonists. Administration of any of the β blockers should be discontinued gradually after chronic treatment to prevent supersensitivity to agonists secondary to the receptor

TABLE 6.5—Pharmacodynamic characteristics and empiric dosage schedules for several β-adrenergic-blocking drugs

Drug	β_1-Receptor block	β_2-Receptor block	ISA*	Half-life† (hr)	Oral dose (mg, TID)	IV dose‡ (mg)
Propranolol	Yes	Yes	No	1–2	5–40	1–5
Timolol	Yes	Yes	No	1–2	0.5–1	0.4–1
Nadolol	Yes	Yes	No	3–8	5–40	. . .
Oxprenolol	Yes	Yes	Yes	≈2	5–40	1–12
Alprenolol	Yes	Yes	Yes	≈2	20–80	5–10
Pindolol	Yes	Yes	Yes	2–4	1–4	0.4–2
Metoprolol	Yes	No§	No	1–2	5–40	. . .
Atenolol	Yes	No§	No	3–6	20–80	. . .
Practolol	Yes	No§	Yes	No longer used	. . .	. . .

Note: The biologic half-life values and dosage ranges for all β-blocking drugs have not been determined for domestic animals under clinical conditions. This table represents an empiric extrapolation based on data from either experimental studies in dogs or clinical studies in humans. Dosage schedules should be considered only as fundamental guidelines, and actual therapy should be implemented with lower dosages while patient response is closely monitored.

*ISA = intrinsic sympathomimetic activity.

†Biologic half-life values vary considerably, and variations among patients regarding therapeutically effective plasma concentrations reach 4- to 20-fold.

‡Intravenous therapy with β blockers to control cardiac dysrhythmias should be done slowly and cautiously with dilute solutions while the electrocardiogram is monitored.

§β_1 selectivity is lost with higher dosages.

"up-regulation" or antagonist-induced receptor sensitivity phenomenon.

In human medicine, many questions remain about the clinical relevance of ISA, receptor up-regulation, and even cardioselective blocking profiles with the β-receptor antagonists. Even less is known about the practical relevance of these aspects in veterinary medicine. Until more data are available, metoprolol or other β_1-selective antagonists should be considered when β-blocking effects are deemed necessary in patients with preexisting pulmonary disease or diabetic-related disorders.

Adrenergic Neuron-Blocking Drugs and Catecholamine-Depleting Agents. These drugs act presynaptically at the adrenergic nerve terminal and prevent release of norepinephrine; they do not block the postsynaptic adrenergic receptor. Therefore, responses to direct-acting sympathomimetic amines are not prevented. However, effects of indirect-acting sympathomimetic amines (agents that cause release of endogenous norepinephrine) are attenuated by neuron-blocking and amine-depleting drugs, since the latter agents affect neuronal mechanisms that are active in the norepinephrine release process. For example, reserpine is a catecholamine-depleting agent that causes a severe reduction of the neuronal stores of norepinephrine. Therefore, less is available for release by an indirect-acting amine such as tyramine. Pressor effects of tyramine are thereby attenuated. Adrenergic neuron-blocking and amine-depleting drugs have not been used in clinical veterinary medicine to any appreciable extent.

Reserpine has been used for treating hypertension and psychic disorders in humans and is extensively used in research as a pharmacologic tool to deplete endogenous catecholamines from peripheral and CNS adrenergic pathways. Chronic daily treatment of dogs with reserpine (approximately 26 μg/kg, administered orally) induces a marked decrease in the concentration of norepinephrine in the hypothalamus, pons-medulla oblongata, and heart (Adams et al. 1971, 1972). Pronounced disturbances in peripheral and central sympathetic functions occur, and myocardial damage has been suspected. The mechanism of action of reserpine is related to an impairment of the Mg^{++}- and ATP-dependent capacity of intraneuronal vesicles to accumulate and store catecholamines. After treatment with reserpine, amines are released from granular storage sites into the neuronal cytoplasm, where they are metabolized by MAO (Shore 1972).

Guanethidine is another agent that depletes catecholamines from adrenergic nerves. However, responses to adrenergic nerve stimulation are inhibited by guanethidine before detectable amine depletion occurs. A local anesthetic-like effect at the adrenergic nerve terminal is thought to be involved. Guanethidine does not effectively pass the blood-brain barrier and has relatively less effect on central adrenergic pathways than reserpine. Guanethidine is used in antihypertensive therapy in humans; propranolol is sometimes given concurrently to block the reflex tachycardia resulting from guanethidine-induced hypotension.

Bretylium is an adrenergic neuron-blocking drug originally used in attempts to control hypertension. Side effects such as postural hypotension precluded the extensive use of this drug in clinical situations. Bretylium is often used in research to prevent the release of norepinephrine from adrenergic nerves. This drug does not deplete adrenergic neurons of their catecholamine stores; in this respect, it is dissimilar to reserpine and guanethidine. Bretylium seems to exert a local anesthetic-like effect at the adrenergic nerve terminal and, by this mechanism, decreases the amount of norepinephrine discharged from the nerve. Interestingly, because of its direct prolonging effect on refractoriness of ventricular tissue, bretylium has been approved for control of certain types of cardiac arrhythmias.

Miscellaneous Agents. A chemical sympathectomy is produced by 6-hydroxydopamine. This compound is taken up into adrenergic nerves and causes anatomic destruction of the nerve terminal. Several weeks are required for regeneration of these structures after treatment with 6-hydroxydopamine.

α-Methyldopa is taken up into the adrenergic nerves, where it is biotransformed by the catecholamine-synthesizing enzymes into α-methylnorepinephrine, which is then stored in the amine granules. The α-methyl group protects this compound from oxidation by MAO. Therefore, endogenous norepinephrine may be displaced from the granule, metabolized by MAO, and replaced by α-methylnorepinephrine. The α-methylnorepinephrine is a potent α_2 agonist, thereby decreasing sympathetic efferent outflow from the CNS.

α-Methyl-para-tyrosine inhibits tyrosine hydroxylase, the rate-limiting enzyme in the synthesis of norepinephrine. Norepinephrine stores are not replenished, and depletion of this amine occurs after cessation of synthesis.

MAO inhibitors are used in humans as mood elevators or antidepressants. These drugs interfere with the oxidative deamination of catecholamines; these amines accumulate in the neuron after treatment with a MAO inhibitor. Responses to peripheral nerve stimulation do not seem to be markedly augmented by MAO inhibitors; however, effects of indirect-acting sympathomimetic amines are markedly potentiated by pretreatment with them. This is due partly to the increased concentration of amine that is available for release by the indirect-acting agent. Hypertensive crises and cerebral vascular accidents have occurred in human patients who ingested tyramine-containing foods (e.g., cheese, wine) while they were taking MAO inhibitors.

Cocaine inhibits the neuronal amine uptake pump of adrenergic nerves. This pump functions to take norepinephrine back up into the nerve. Other amines (e.g., tyramine) gain access into the neuron by this uptake mechanism. Thus cocaine potentiates the effect of norepinephrine but blocks the effect of tyramine. Imipramine and desmethylimipramine are tricyclic antidepressants; they, too, block the neuronal amine uptake mechanism.

Acetylcholine (ACh) acts as the messenger between nerve endings and innervated cells of autonomic ganglia, parasympathetic neuroeffector junctions, some sympathetic neuroeffector junctions, somatic neuromuscular junctions, the adrenal medulla, and certain regions of the central nervous system (CNS). It has been recognized for many years that considerable therapeutic benefit could be derived from drugs that would selectively mimic the action of ACh only at certain of these sites or, alternatively, that could selectively prevent only unwanted effects of this biogenic substance. Although ideal drugs have yet to be identified, some agents have been found to be relatively more active at certain cholinergic sites than at others. In this chapter, drugs that influence postganglionic parasympathetic neuroeffector junctions and autonomic ganglia by ACh-like or ACh blocking effects will be examined. Parasympathetic neurons and affiliated receptors of innervated cells are depicted in Fig. 7.1.

PARASYMPATHOMIMETIC AGENTS. "Cholinergic" is used to describe an ACh-like effect without distinction as to anatomic site of action. "Parasympathomimetic" is used specifically to describe an ACh-like effect on effector cells innervated by postganglionic neurons of the parasympathetic nervous system (Fig. 7.1). Most of the cholinergic drugs considered here are used clinically for their parasympathomimetic activities. However, the scope of pharmacologic activity of several of these compounds is not restricted to parasympathomimetic effects but includes cholinergic actions throughout the body.

Based on mechanism of action, drugs that cause parasympathomimetic effects can be divided into two major groups: direct-acting agents, which like ACh activate cholinergic receptors of the effector cells, and cholinesterase inhibitors, which allow endogenous ACh to accumulate and thereby intensify and prolong its action.

DIRECT-ACTING PARASYMPATHOMIMETIC AGENTS. Direct-acting parasympathomimetic agents consist of esters of choline and naturally occurring cholinomimetic alkaloids.

Choline Esters. Choline, a member of the B vitamin group, possesses the characteristic depressor action of a cholinergic drug when injected intravenously in large unphysiologic amounts; however, its potency is multiplied thousands of times when it is esterified with acetic acid to yield ACh.

ACh, although essential for maintenance of body homeostasis, is not used therapeutically for two important reasons. First, it acts simultaneously at various tissue sites and no selective therapeutic response can be achieved. Second, its duration of action is quite brief because it is rapidly inactivated by the cholinesterases. Several derivatives of ACh are more resistant to hydrolysis by cholinesterase and have a somewhat greater selectivity in their sites of action. Of several hundred choline derivatives that have been synthesized, carbachol, bethanechol, and methacholine have proved effective for certain clinical uses and will be discussed here.

MECHANISM OF ACTION. Pharmacologic effects of ACh and related choline esters are mediated by activation of specific ACh-responsive sites (i.e., cholinergic receptors or cholinoceptors) located on cells innervated by cholinergic nerves and, in some cases, on cells that lack cholinergic innervation. Choline esters act directly on postsynaptic receptors and do not depend upon endogenous ACh for their effects. Based on differential responsiveness to cholinergic agonists and antagonists, two basic types of cholinoceptors have been identified

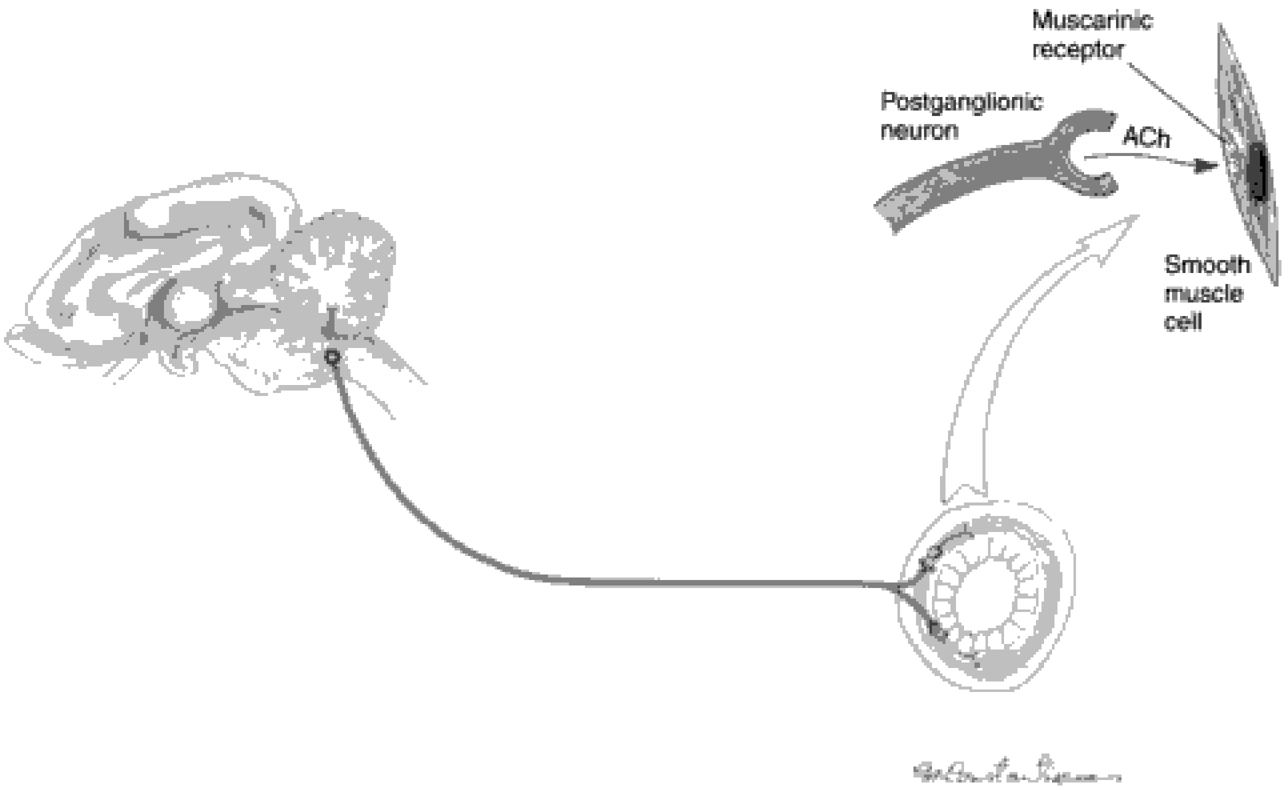

FIG. 7.1.—Anatomical relationships of parasympathetic neuronal outflow tracts and affiliated receptors of innervated cells. Parasympathetic preganglionic axons exit cranial (shown) or sacral zones and pass peripherally to synapse with a neuron body located within (shown) or adjacent to innervated tissue. The preganglionic neuron releases the neurotransmitter acetylcholine (ACh), which activates nicotinic cholinergic receptors on the ganglionic neuron body. The resulting stimulation of the ganglionic neuron promotes release of ACh from the axon terminal at postganglionic parasympathetic neuroeffector junctions within the intestinal tract (shown) or other tissues innervated by parasympathetic neurons. ACh activates muscarinic cholinergic receptors present on cells innervated by the parasympathetic division of the autonomic nervous system. Preganglionic fibers are red; postganglionic fibers are blue. Drawn by Dr. Gheorghe M. Constantinescu, University of Missouri. (*See also color plates following p. 118.*)

within the peripheral efferent pathways of the mammalian autonomic nervous system (Fig. 7.1).

NICOTINIC RECEPTORS. Beginning with the early studies by Dale (1914), it was known that nicotine in small doses mimics certain actions of ACh and in larger doses blocks these same cholinergic effects. As summarized in Chap. 5, nicotinic responsive sites are present in autonomic ganglia, adrenal medullary chromaffin cells, and neuromuscular junctions of the somatic nervous system. Accordingly, receptors at these sites are called nicotinic cholinergic receptors, and effects of cholinergic drugs at these sites are described as nicotinic effects. Nicotinic receptors at ganglia are different subtypes from those localized to voluntary skeletal muscle.

MUSCARINIC RECEPTORS. Nicotine does not mimic ACh at postganglionic parasympathetic neuroeffector junctions, i.e., parasympathetic innervation to heart muscle, smooth muscle, and exocrine glands. The mushroom alkaloid muscarine was found to selectively mimic activity of ACh at these sites, but not at the previously mentioned nicotinic receptors. Muscarinic receptors, therefore, designate the type of cholinoceptors present at postganglionic parasympathetic neuroeffector junctions (Fig. 7.1). Muscarinic receptors are also present in some blood vessels that lack cholinergic innervation and at neuroeffector junctions of the sympathetic nervous system that are cholinergic (see Chap. 5). The parasympathomimetic, or muscarinic, effects produced by drugs examined in this chapter are equivalent to the physiologic changes evoked by postganglionic parasympathetic nerve impulses, as listed in Table 5.1.

Atropine is a cholinergic blocking agent that selectively blocks muscarine receptors without blocking nicotinic sites; whereas hexamethonium, *d*-tubocurarine, and large doses of nicotine block nicotinic but not muscarinic receptors.

ACh evokes an excitatory response in some tissues, e.g., smooth muscle of the gastrointestinal (GI) tract, but causes inhibitory responses in other tissues, e.g., myocardium. In general, excitatory effects of ACh are due to depolarization of the postsynaptic membrane characterized by an increase in permeability of the membrane to both Na^+ and K^+ ions. Inhibitory effects have been associated with an inhibitory G protein (i.e.,

G_i) linked to diminution of adenylyl cyclase and resulting decreased formation of cAMP and protein kinase A (Lambert 1993). In some tissues, muscarinic receptors are linked to activation of guanylyl cyclase with increased formation of cGMP (Lefkowitz et al. 1990; Lambert 1993).

STRUCTURE-ACTIVITY RELATIONSHIPS. Direct-acting cholinergic agonists contain structural groupings that allow interaction of the agent with cholinergic receptors and result in similar changes in membrane configuration and thus ion permeability as caused by ACh (Rand and Stafford 1967). Choline esters contain a quaternary nitrogen atom to which three methyl groups are attached. Except for some naturally occurring cholinomimetic alkaloids, a quaternary nitrogen moiety is usually required for a direct potent action on cholinergic receptors. Like its counterpart the ammonium ion, the quaternary nitrogen group carries a positive charge; this cationic group electrostatically binds with a negatively charged (anionic) site of the cholinergic receptor. The anionic site is believed to be the main determinant of receptor events, and interaction of the cationic head of ACh with the anionic site is the primary instigator of conformational changes that lead to alterations in membrane permeability.

Receptive macromolecules (i.e., cholinergic receptors and cholinesterases) that recognize and bind ACh have, in addition to the anionic site, a region that combines with the ester component of ACh (Fig. 7.2) (Hucho et al. 1991). In cholinesterase, this region is called the esteratic site and its combination with the carboxyl group results in hydrolysis of the ester (see discussion later in this chapter). Hydrolysis of ACh does not occur upon its interaction with a receptor, however, and the ester-attracting region of the receptor is called the esterophilic site (Inestrosa and Perelman 1990; Taylor 1990a, 1991; Massoulie et al. 1993).

ACh is ideally arranged structurally so that it combines with the esterophilic and anionic sites of both nicotinic and muscarinic receptors and acetylcholinesterases (Hucho et al. 1991). When both components of the ester moiety of ACh (i.e., the carbonyl group and the ether oxygen) are replaced by methylene molecules, agonistic properties at both muscarinic and nicotinic sites are reduced. If only the ether oxygen of ACh is substituted by a methylene group, the muscarinic potency is markedly decreased but nicotinic properties are little affected. Introduction of a methyl group on the β-carbon atom of the choline segment considerably reduces nicotinic properties but does not reduce muscarinic activities. These findings indicate that the esterophilic sites are arranged somewhat differently in muscarinic than in nicotinic receptors and therefore influence specificity of agonistic and antagonistic properties of different drugs. The esterophilic region may contain subunits that individually attract either the ether oxygen or the carbonyl oxygen by hydrogen bonding and dipole-dipole interaction respectively (Fig. 7.2B) (Khromov-Borisov and Michelson 1966).

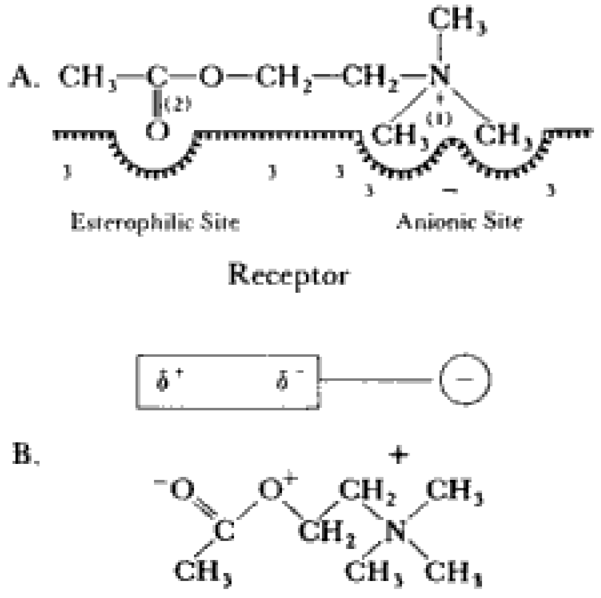

FIG. 7.2—Interaction of ACh and its receptor. **A.** (1) = electrostatic bond between cationic (quaternary N⁺) group of ACh and the anionic site of the receptor. (2) = dipolar binding of ester of ACh with the esterophilic site of the receptor [note: in ACh-cholinesterase interaction, (2) = covalent bonding of carboxyl carbon to a protonated acidic group of the esteratic site of the enzyme]. (3) = probable existence of hydrophobic bonds between the various methyl groups and adjacent proteins of the receptor surface. Based on the postulated interaction of ACh and cholinesterase (modified from Eldefrawi 1974). **B** Electrical charge distribution of ACh and its receptor (Khromov-Borisov and Michelson 1966).

ACh is the prototypical cholinergic agent; it acts at all cholinoceptor sites and therefore evokes both nicotinic and muscarinic effects. Acetyl-β-methylcholine (methacholine) is identical in structure to ACh except for the substitution of a methyl group on the β-carbon atom of the choline group. This structural change yields a compound that is primarily a muscarinic receptor agonist lacking significant nicotinic effects when given in usual dosages. Further, it is more active on the cardiovascular system than on the GI tract. Duration of action of methacholine is considerably longer than that of ACh because the former drug is hydrolyzed by acetylcholinesterase (AChE) at a much slower rate than is ACh and methacholine is almost totally resistant to breakdown by pseudocholinesterase.

Carbachol and bethanechol each have a carbamyl (NH_2COO-) group substituted for the acetic moiety of ACh, and bethanechol also has a β-methyl group. Both of these agents are almost completely resistant to inactivation by the cholinesterases. Their duration of action is therefore considerably longer than that of ACh. Carbachol is active at both muscarinic and nicotinic receptor sites (therefore it is cholinomimetic and not just parasympathomimetic), whereas bethanechol is primarily a muscarinic agonist. Unlike methacholine, both these drugs are somewhat more active on smooth muscles of the GI tract and urinary bladder than on

TABLE 7.1—Chemical structures (A) and scope of cholinergic receptor activating properties (B) of some choline esters

A.	Compound	Structure
	Choline	$(CH_3)_3N^+ \cdot CH_2 \cdot CH_2 \cdot OH$
	Acetylcholine	$(CH_3)_3N^+ \cdot CH_2 \cdot CH_2 \cdot O \cdot COCH_3$
	Methacholine	$(CH_3)_3N^+ \cdot CH_2 \cdot CH_2 \cdot O \cdot COCH_3$
	Carbachol	$(CH_3)_3N^+ \cdot CH_2 \cdot CH_2 \cdot O \cdot CONH_2$
	Bethanechol	$(CH_3)_3N^+ \cdot CH_2 \cdot CH(CH_3) \cdot O \cdot CONH_2$

cardiovascular function. Chemical structures of these choline esters and their related pharmacologic characteristics are shown in Table 7.1.

ACETYLCHOLINE. Although ACh is not used clinically, it is the prototypical cholinergic agonist, and an understanding of its activity is imperative for a comprehension of the pharmacologic effects of other cholinomimetic drugs. The biosynthesis, neuronal release, cellular activities, and inactivation of endogenous ACh are examined in Chap. 5 and should be reviewed in conjunction with this chapter.

Since ACh is a mixed nicotinic-muscarinic agonist, different effects can be produced by administration of this agent, depending upon the relative dominance of muscarinic (parasympathomimetic) or nicotinic actions. These effects can be differentiated by use of small and large doses of ACh and by using selective cholinergic blocking drugs. In general, parasympathomimetic effects dominate with small doses, whereas with large doses cholinergic effects at other tissue sites are also produced. Therefore, muscarinic receptors seem to be more susceptible than nicotinic receptors to ACh. Use of cholinergic blocking drugs and small and large doses of ACh to differentiate muscarinic and nicotinic effects of ACh is shown in Fig. 7.3. This figure is discussed in greater detail in the following sections.

PHARMACOLOGIC EFFECTS

Cardiovascular Effects of Small Doses of ACh. Intravenous (IV) administration of small amounts of ACh (5-10 μg/kg) produces a brief but rapid fall in systolic and diastolic blood pressures. This is due to a decrease in peripheral resistance resulting from dilation of blood vessels. Most blood vessels receive little or no parasympathetic innervation (see Chap. 5). Therefore, most vascular smooth muscle is different from other smooth muscle in that its muscarinic receptors are noninnervated.

Interestingly, muscarinic receptors subserving dilation of blood vessels are located on the endothelium rather than on the smooth muscle itself. Activation of endothelial muscarinic receptors by ACh causes the endothelial cells to release endothelium-derived relaxing factor (EDRF) (Furchgott and Zawadzki 1980), identified as nitric oxide (Lowenstein et al. 1994). Nitric oxide transfers to the vascular smooth muscle cells and therein activates cytosolic guanylyl cyclase; the resulting increase in cGMP provokes vascular smooth muscle relaxation and vasodilation, as summarized in Fig. 5.8 (Adams 1996).

Somewhat larger doses of ACh (10-30 μg/kg) produce pronounced muscarinic effects; therefore, a pronounced decrease in peripheral resistance and blood pressure is produced. In addition to the hypotension response, a slowing of the heart rate occurs after administration of ACh (a transient tachycardia may initially occur from the hypotensive response affecting baroreceptor reflex activity). Atrial myocardial cells contain muscarinic receptors associated with vagal fibers that mediate negative chronotropic and inotropic effects. The chronotropic effects predominate; they are due to a decreased slope of phase 4 (spontaneous depolarization) of the pacemaker action potential of the sinoatrial (SA) node.

ACh, in addition to its pronounced slowing effect on heart rate, exerts important effects on impulse conduction. In the atria, cholinergic activation slows conduction velocity but shortens action potential duration and the effective refractory period. These actions reinforce atrial dysrhythmias and lead to atrial flutter and fibrillation. In the atrioventricular (AV) node, however, ACh slows conduction velocity but prolongs the refractory period. Thus, although cholinergic drugs can exacerbate atrial tachyarrhythmias, the number of aberrant impulses that effectively traverse the AV junction into the ventricular cells can be decreased concomitantly by the same agent. The net effect is a slowing of ventricu-

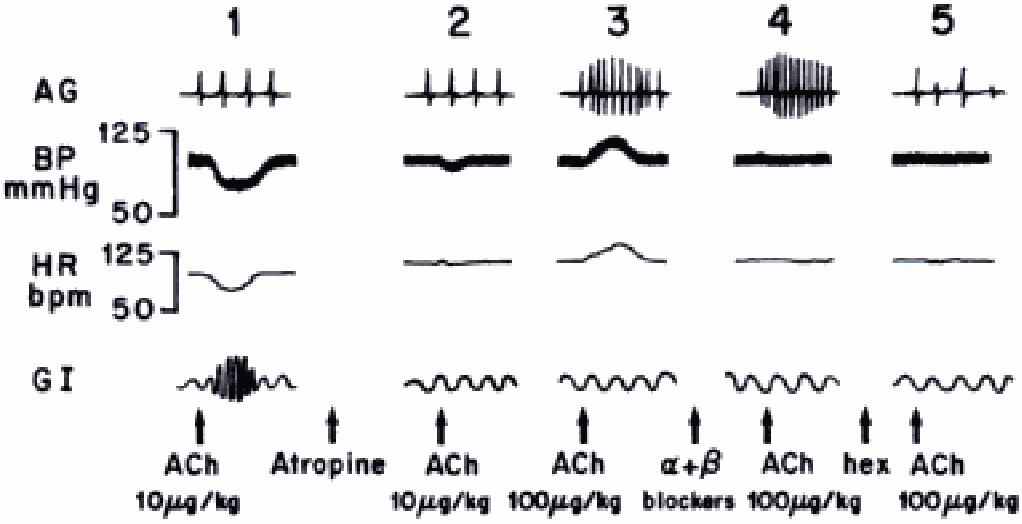

FIG. 7.3—Muscarinic and nicotinic effects of ACh on blood pressure, heart rate, intestinal motility, and autonomic ganglionic action potentials in an anesthetized dog. Schematic reproductions: 1. A small dose of ACh (10 µg/kg) administered intravenously causes hypotension, bradycardia, and intestinal contractions caused by direct stimulation of muscarinic receptors of blood vessels, heart, and intestinal smooth muscle respectively. These effects are brief because of rapid destruction of ACh by cholinesterase. 2. Atropine blocks the muscarinic receptors and thereby prevents the effects seen in (1). 3. Large doses of ACh (100 µg/kg) stimulate, in addition to muscarinic receptors, nicotinic receptors of parasympathetic and sympathetic ganglionic neurons, causing an increase in frequency and amplitude of ganglionic action potentials. Although all autonomic ganglia are activated, impulses arising from parasympathetic ganglia do not reach their effector cells because of blockade of parasympathetic postganglionic neuroeffector junctions by atropine. Sympathomimetic responses (pressor effect and tachycardia) result. 4. Impulses arising from sympathetic ganglia are prevented from reaching their effector cells by adrenergic blocking drugs; however, ganglionic nicotinic receptors are still activated by ACh. 5. Hexamethonium (hex) blocks nicotinic receptors of ganglia and thereby inhibits the nicotinic ganglionic stimulating effect of ACh and reduces ganglionic action potentials. AG = action potentials of autonomic ganglionic neuron; BP = systemic blood pressure; HR = heart rate; GI = intestinal peristaltic waves.

lar rate; this mechanism has pharmacologic importance, because the beneficial slowing effects of digitalis on ventricular rate in patients with atrial fibrillation or flutter is mediated in part by increased vagal tone.

Different arrhythmias that can result from use of cholinergic drugs include sinus arrest, severe bradycardia, incomplete and complete heart block, notching and decreased amplitude of the P wave, momentary ventricular asystole, and atrial fibrillation and flutter.

Smooth Muscle. GI motility and secretions are enhanced by ACh in a manner identical to that seen upon stimulation of the parasympathetic innervation to the alimentary tract. These effects may be difficult to detect with small doses because duration of action of ACh is brief owing to rapid destruction by cholinesterase. Larger doses markedly increase secretions and peristaltic movements of the GI tract.

ACh stimulates smooth muscle of the urinary bladder and uterus to contract. Bronchiolar smooth muscle is also contracted by ACh, resulting in decreased diameter of airways. The smooth muscle effects of ACh are blocked by atropine and therefore are due to muscarinic receptor activation.

Central Nervous System. Because of its highly charged quaternary nitrogen group, ACh is lipophobic and poorly penetrates cell membranes and the blood-brain barrier. Thus CNS effects are not observed when usual dosages are administered. However, intra-arterial injection into cerebral arteries of large amounts of ACh or its direct application into the CNS produces increased electrical activity, excitation, and possibly convulsions. Both muscarinic and nicotinic receptors are present in the CNS.

Muscarinic and Nicotinic Effects of Large Doses of ACh. With high doses (50-100 µg/kg), muscarinic effects of ACh on postganglionic effector cells are accentuated. Profound hypotension is caused by extensive peripheral vasodilation. Duration of this effect is prolonged. Heart rate slows dramatically and momentary asystole can occur. The GI tract and other visceral smooth muscles are markedly activated; defecation, urination, and vomiting may result.

Large doses of ACh produce, in addition to the muscarinic (i.e., parasympathomimetic) effects described above, stimulation of the nicotine receptors of autonomic ganglia (both parasympathetic and sympathetic) and the adrenal medulla. These effects are particularly evident when the muscarinic receptors of the parasympathetic neuroeffector junctions are blocked by atropine. Under these circumstances large doses of ACh stimulate nicotinic receptors of both sympathetic and parasympathetic ganglia. However, because the muscarinic receptors of the parasympathetic neuroeffector junctions are blocked by atropine, impulses originating from parasympathetic ganglia will not reach their effector cells. Only impulses originating from sympathetic ganglia will do so; therefore, only sympathomimetic responses will be evident. These are characterized by an increase in blood pressure, tachycardia, and other typical sympathetic-mediated effects, which can be blocked by use of appropriate adrenergic blocking drugs (see Chap. 6) or by use of a ganglionic blocking agent (Fig. 7.3).

Adrenal Medulla. The adrenal medulla is functionally analogous to autonomic ganglia, and nicotinic receptors of adrenal medullary chromaffin cells are innervated by typical preganglionic cholinergic fibers. These receptors are stimulated by ACh to cause release of epinephrine and norepinephrine from chromaffin cells into the circulation. This effect contributes to the overall nicotinic-mediated sympathomimetic effect evoked by large doses of ACh in the presence of muscarinic blockade.

Skeletal Muscle. Intra-arterial injection of significant quantities of ACh will produce skeletal muscle fasciculations caused by penetration of some of the agent to motor end-plates and resulting activation of nicotinic receptors of skeletal muscle cells. Continued exposure to excessive amounts of ACh causes severe fasciculations and asynchronous contractions and terminates in a depolarizing paralysis. Also, if an atropine-like drug has not been given, an increase in blood flow to the injected muscle occurs as a result of vasodilation from stimulation of the muscarinic receptors of blood vessel endothelial cells and the resulting release of EDRF.

METHACHOLINE, CARBACHOL, AND BETHANECOL. The pharmacologic effects of these choline esters are equivalent to the previously outlined parasympathomimetic effects of ACh and thus are similar to the physiologic changes evoked by stimulation of postganglionic parasympathetic nerves as listed in Table 5.1. Carbachol also has marked nicotinic agonistic characteristics; however, differences between the parasympathomimetic actions of these choline esters are primarily quantitative and vary principally in relative selectivity for one organ system or another (Table 7.1).

Methacholine (acetyl-β-methylcholine) is a synthetic choline ester used occasionally in human therapeutics but infrequently employed in veterinary medicine. Methacholine causes muscarinic effects on cardiovascular function similar to those produced by ACh, but it is considerably less active on the GI system and has few agonist properties at nicotinic receptors.

Carbachol (Lentin, carbamylcholine chloride, Doryl) is an extremely potent choline ester that is active at both muscarinic and nicotinic receptors and therefore causes pharmacologic effects similar to changes evoked by ACh. These are particularly prominent on the nicotinic receptors of autonomic ganglia; however, this drug is also very potent at muscarinic sites. For example, IV injection of doses as small as 2 μg/kg causes a transient slowing of heart rate and hypotension owing to muscarinic effects.

Bethanecol (Urecholine, carbamylmethylcholine) is somewhat similar to methacholine and carbachol in scope of pharmacologic activity. Unlike carbachol, however, it is primarily a muscarinic agonist and has little stimulant effects on nicotinic receptors.

PHARMACOLOGIC EFFECTS

Cardiovascular Effects. Methacholine is more active on the cardiovascular system than on the GI or urinary tracts. The opposite selectivity is seen with carbachol and bethanechol. IV administration of methacholine, like ACh, produces a depressor response and slowing of heart rate caused by activation of muscarinic receptors of blood vessels and the heart respectively. Cardiac rhythm is altered by methacholine, and the AV node is particularly sensitive to this agent. Conduction velocity through the AV node is decreased. Various degrees of heart block, including complete AV disassociation, can occur with large doses. IV administration of methacholine to normal nonanesthetized animals can produce atrial fibrillation, as can ACh. These effects are blocked by atropine. Carbachol evokes blood pressure changes similar to those seen with methacholine except relatively less pronounced, whereas bethanechol is considerably less active on cardiovascular function.

GI Tract. Carbachol and bethanecol are relatively more active on the GI and urinary tracts than on the cardiovascular system. Methacholine is also active on the alimentary canal but only in large doses. Carbachol is a potent GI stimulant. It evokes profuse salivation and an increase in peristaltic movements of the gut resulting in increased fluidity of feces and defecation. These responses are due to activation of muscarinic receptors. GI stimulant effects of choline esters are relatively well defined in simple-stomached animals, but responsiveness of ruminants may vary. Effects of carbachol and various other autonomic drugs on the GI tract of ruminants are summarized in previous editions of this text.

Other Smooth Muscle. Uterine musculature, in in vitro strips and the intact animal, is contracted by carbachol. This response is more evident during the latter stages of gestation. Carbachol should not be used during pregnancy, because abortion or uterine rupture might result. After parturition, carbachol may be useful in expelling uterine contents.

Similar to ACh, carbachol causes contraction of bronchiolar smooth muscle, resulting in a decreased airway. The urinary bladder is contracted by carbachol and bethanechol, and frequent urination results. Effects of carbachol and bethanechol on these as on other smooth muscles are muscarinic and blocked by atropine.

Skeletal Muscle. Carbachol does not discernibly affect skeletal muscle when usual dosages are employed. If a high dose is inadvertently given, muscle fasciculations and even paralysis may occur. This is a nicotinic effect due to carbachol causing a persistent depolarization block of the postjunctional membrane of the neuromuscular junction. Because of relative lack of agonistic effects at nicotinic sites, bethanechol and methacholine have little effect on voluntary muscles.

Sweating. Profuse sweating in the horse is evoked by carbachol. It is not known if this is due to a direct effect on sweat glands, a ganglionic stimulating effect, an increase in circulating catecholamines (as a result of adrenal medullary stimulation), or local release of catecholamines from adrenergic neurons. Because sweat gland mechanisms in the horse seem to be β_2 adrenergic (Bijman and Quinton 1984), either of the latter two mechanisms could be involved.

Other Effects. Carbachol, like ACh, is a mixed nicotinic-muscarinic agonist. It therefore has a potent stimulating effect on autonomic ganglia and the chromaffin cells of the adrenal medulla. Such an effect on the adrenal medulla would cause an increased discharge of epinephrine and norepinephrine into the bloodstream, which in turn could produce diffuse sympathomimetic effects. This relationship may explain why adrenergic-like effects have occasionally been encountered during the use of carbachol. Nicotinic effects of carbachol on autonomic ganglia can be demonstrated by the hypertensive response obtained with large doses after the postganglionic muscarinic receptors have been blocked with atropine (Fig. 7.3).

CLINICAL USES. Methacholine and bethanechol are not used frequently in clinical veterinary medicine. Methacholine has been used in humans and animals to produce peripheral vasodilation in treating different vascular disorders such as Raynaud's disease and ergot poisoning respectively. It has been used in human medicine to control tachycardia of supraventricular origin. Ventricular tachycardia and nodal paroxysmal tachycardia (in which the origin is in the AV node) are not amenable to methacholine therapy. Bethanechol, 1 mg administered subcutaneously twice daily, has been used to treat urinary bladder atony in cats after incidences of urolithiasis; however, care should be taken to ensure that the urethra is completely patent.

Carbachol is a potent drug, and care should be taken to avoid overstimulation of the GI tract and uterus during its clinical use. It has been used for treatment of colic and impactions of the intestinal tract; however, its use in such cases should be closely monitored. If excessive peristaltic movements are induced in a patient suffering from intestinal obstruction, rupture or intussusception may occur. Before resorting to a potent cholinomimetic compound such as carbachol, consideration should first be given to more conservative approaches to GI therapy such as the use of mineral oil, saline cathartics, water, or other stool softeners. If these measures are not successful, carbachol may be cautiously added to the therapeutic regimen. Repeated small subcutaneous (SC) doses of 1-2 mg carbachol at 30- to 60-minute intervals have been used in treating colic in mature horses after treatment with oils and saline cathartics had been instituted. Dosages should be decreased to 0.25-0.5 mg in foals.

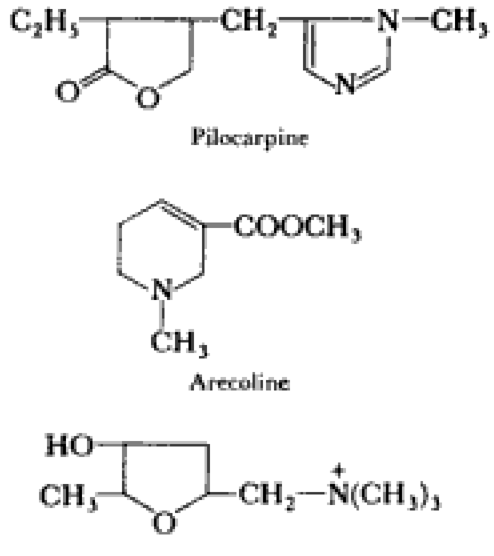
When administered during the middle of farrowing, carbachol (2 mg subcutaneously) has been reported to decrease the incidence of stillbirths in litters from sows and gilts by increasing uterine contractions (Sprecher et al., 1975). However, severe salivation, vomiting, diarrhea, and frequent urination were adverse side effects.

Carbachol has been used in treatment of rumen atony and impaction in cattle. After conservative treatment with stool softeners, repeated doses of 1-2 mg have proved effective in stimulating rumen motility. However, single doses greater than 4 mg may be ineffective and in some cases may actually inhibit ruminoreticular activity. Carbachol should not be given by IV or, probably, intramuscular (IM) injection because of its potency. It is given by the SC route; however, the dosage is still critical. Fatalities have occurred in human patients after IM injection of carbachol.

Naturally Occurring Cholinomimetic Alkaloids. Pilocarpine, muscarine, and arecoline are plant alkaloids that exert parasympathomimetic effects with minimal activity at nicotinic sites. Although all three agents are used in research, only pilocarpine has been used to any appreciable extent in clinical medicine.

Pilocarpine nitrate is the water-soluble salt of the alkaloid pilocarpine, obtained from leaves of the Brazilian shrubs *Pilocarpus jaborandi* and *P. microphyllus.* Arecoline is an alkaloid found in the betel nut, the seed of the betel palm *(Areca catechu).* Muscarine is found in the poisonous mushrooms *Amanita muscaria.* The chemical structures of these three compounds are given in Fig. 7.4.

PHARMACOLOGIC MECHANISMS AND EFFECTS. Pilocarpine, arecoline, and muscarine are rather selective parasympathomimetic agents; i.e., their cholinomimetic activity is exerted primarily at muscarinic sites with minimal nicotinic effects. Even the slight ganglionic-stimulating effects of pilocarpine and arecoline are believed to be from activation of the secondary muscarinic pathway involved in ganglionic transmission (see latter part of this chapter). These cholinomimetic alkaloids evoke their parasympathomimetic effects by direct stimulation of the muscarinic receptors of cells innervated by postganglionic cholinergic nerves. They do not inhibit cholinesterase. Also, because their effects are produced in chronically denervated tissue, they are not dependent upon release of endogenous ACh.



Pilocarpine

Arecoline

Muscarine

FIG. 7.4

Pilocarpine is particularly effective in stimulating flow of secretions from exocrine glands, including salivary, mucous, gastric, and digestive pancreatic secretions. As with ACh it causes contraction of GI smooth muscle, thereby increasing smooth muscle tone and peristaltic activity. Of considerable importance, pilocarpine has a potent constrictor effect on the pupil.

Arecoline activates muscarinic receptors of cholinergically innervated effector cells of glands, smooth muscles, and myocardium and therefore produces the usual parasympathomimetic effects. It is similar to pilocarpine in scope of activity but is considerably more potent. Arecoline depresses heart rate and blood pressure and may produce dyspnea by constricting the bronchioles. Dyspnea generally is not marked except in cases where the dose is toxic or the animal has previously been affected with a respiratory ailment such as acute pulmonary emphysema. Arecoline stimulates secretion of the glands of the digestive tract and increases peristaltic movements of the gut. Increased flow of saliva, occurring within 5 minutes following a SC injection and lasting for an hour, is particularly noticeable. Arecoline contracts the urinary bladder.

Muscarine has been employed experimentally for many years because it has a selective excitatory effect on the effector cells of tissues innervated by postganglionic cholinergic nerves. It does not stimulate the nicotinic receptors of autonomic ganglia or skeletal muscle as does ACh.

CLINICAL USES. Pupillary constriction (miosis) occurs when pilocarpine is administered systemically or applied topically to the eye. Clinically, solutions of 0.5-2% are used for instillation into the conjunctival sac for treatment of glaucoma. Pilocarpine stimulates the sphincter muscle of the iris and the ciliary muscle of the lens, causing pupillary constriction and spasm of accommodation. Intraocular pressure momentarily increases, followed by a persistent decrease. Fixation of the lens for near vision lasts only 1-2 hours; however, miosis, which develops within about 15 minutes after instillation, persists 12-24 hours. Pilocarpine is also used alternately with mydriatics to prevent synechiation, but it is contraindicated in patients with iridocyclitis.

TOXICOLOGY. Toxic doses of the cholinomimetic alkaloids evoke severe colic and diarrhea and exocrine gland secretions. The pupil is markedly constricted. Dyspnea occurs because of constriction of the bronchioles and accumulation of mucus in the airways. Hypotension and extreme cardiac slowing, complicated by excessive bronchoconstriction and bronchial secretions, lead to death. Arecoline or systemic exposure to pilocarpine is contraindicated in animals with heart failure, depression or disease of the respiratory tract, and spasmodic colic and during gestation. Atropine is a specific antidote to toxic doses of arecoline, pilocarpine, and muscarine. Toxic action of the poisonous mushroom in humans results from the parasympathomimetic action of muscarine.

CHOLINESTERASE INHIBITORS. The function of AChE in terminating the transmitter action of endogenous ACh at cholinergic synapses and neuroeffector junctions is discussed in Chap. 5. Cholinesterase inhibitors (anticholinesterase agents) inactivate or inhibit AChE and pseudocholinesterase and thereby intensify activity of endogenous ACh. In addition, the activity of drugs that are biotransformed by cholinesterase (e.g., succinylcholine) is also prolonged by cholinesterase inhibitors. Because these drugs magnify the actions of endogenous ACh at all cholinergic receptors, their scope of activity is not limited to parasympathomimetic effects but includes cholinomimetic actions throughout the body.

Physostigmine, neostigmine, and edrophonium are examples of the type of anticholinesterase agent that produces a reversible inhibition of cholinesterase, whereas organophosphate compounds such as diisopropyl fluorophosphate (DFP) produce an irreversible inhibition. Although there is considerable distinction between these two groups of anticholinesterases, their pharmacologic effects are similar because of a common basic mechanism of action.

Pharmacologic Considerations

MECHANISM OF ACTION. The pharmacologic effects of cholinesterase inhibitors can be explained almost entirely by their characteristic inhibitory action on AChE. This results in decreased hydrolysis of neuronally released ACh and intensification of its action at cholinergic receptors. This is particularly true with the irreversible organophosphate compounds and can be demonstrated by lack of miotic effect of topically

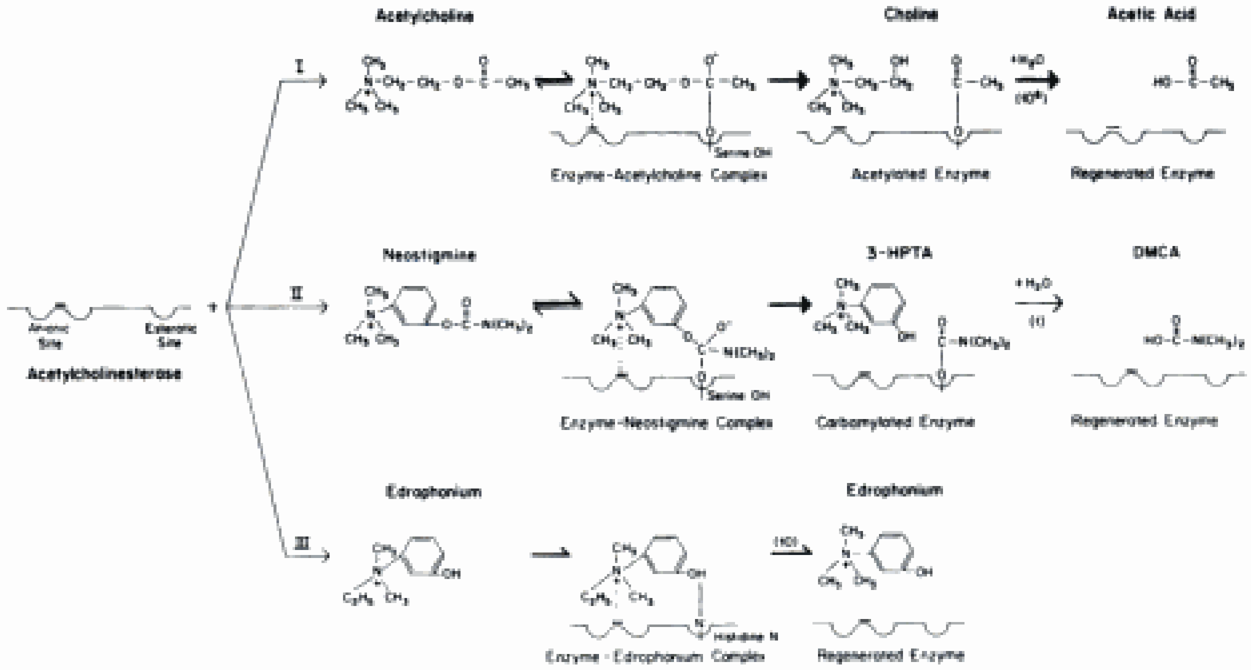


FIG. 7.5—Interaction of ACh, neostigmine, and edrophonium with AChE. I. ACh complexes with AChE via electrostatic binding of the quaternary (cationic) N^+ of the choline group with the anionic site of the enzyme and by interaction of the carbonyl group with a serine hydroxyl group of the esteratic site. Choline is split off, yielding the acetylated enzyme, which interacts with H_2O to yield acetic acid and the reactivated enzyme. II. Neostigmine complexes with AChE to yield 3-hydroxyphenyltrimethylammonium (3-HPTA) and carbamylated enzyme, which then react with H_2O to give *N,N*–dimethylcarbamic acid (DMCA) and the reactivated enzyme; this reaction is = 10^{-6} slower than the comparable reaction involving ACh and AChE. III. Edrophonium complexes with AChE via electrostatic interaction at the anionic site and by H bonding to the imidazole N atom of histidine at the esteratic site; this complex is reversible, yielding reactivated AChE and edrophonium. The numbers in parentheses refer to relative rates of reaction (Taylor 1990a; Inestrosa and Perelman 1990; Massoulie et al. 1993).

applied DFP in a chronically denervated eye, where there is no source of ACh. Neostigmine and other quaternary nitrogen anticholinesterase agents exert some direct effects (either agonistic or antagonistic) on cholinergic receptors in addition to inhibition of cholinesterase. At the somatic neuromuscular junction, e.g., muscle twitch stimulant effects of neostigmine are attributed to direct receptor activation as well as to cholinesterase inhibition. The direct effect is not uniform throughout the body. Neostigmine, like DFP, is miotically inactive in the denervated eye. Effects of physostigmine, a tertiary amine, can be explained almost entirely by its anticholinesterase activity.

MOLECULAR. The enzymatic interactions of AChE, ACh, and cholinesterase inhibitors are shown schematically in Fig. 7.5 and can be summarized as follows (Taylor 1990a, 1991; Inestrosa and Perelman 1990; Massoulie et al. 1993). AChE contains two active sites that recognize specific parts of the ACh molecule: an anionic (negatively charged) region where electrostatic binding occurs with the cationic nitrogen of the choline moiety, and an esteratic site where the carboxyl portion of the acetyl ester binds to it by covalent bonding. After ACh-AChE interaction occurs, the choline portion is split off, leaving the acetylated esteratic site. Acetic acid is rapidly formed as water reacts with the acetyl group, and the enzyme is thereby reactivated (Wilson 1954).

Neostigmine, physostigmine, and other carbamate derivatives interact with the anionic and esteratic sites of the enzyme, thereby preventing ACh from affixing to the enzyme. Neostigmine and physostigmine are believed to be hydrolyzed in a manner similar to but much slower than that of ACh (Wilson et al. 1960); i.e., the alcoholic portion of the anticholinesterase compound is split off, leaving a carbamylated esteratic site. A carbamic acid is then formed upon reaction with water, and the enzyme is regenerated (Fig. 7.5). Although the rate of combination of inhibitor with AChE is only a few times slower than the analogous combination of ACh with the enzyme, the rate of hydrolysis is probably over 10^6 times faster for ACh. Therefore, neostigmine and related drugs are reversible cholinesterase inhibitors as a result of their acting as competitive substrates hydrolyzed at a much slower rate than the endogenous substrate ACh (Taylor 1990a, 1991; Massoulie et al. 1993).

Edrophonium and tetraethylammonium ions are complex and simple quaternary nitrogen compounds respectively that interact with the anionic site of cholinesterase. Therefore, they are not hydrolyzed but act as simple competitive reversible inhibitors. Accordingly, the duration of action of edrophonium is much shorter than that of neostigmine or physostigmine.

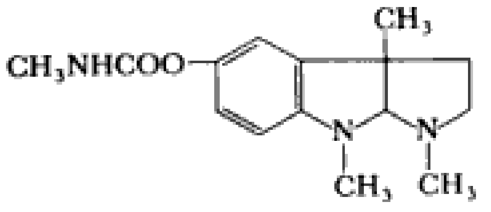
Organophosphate compounds interact with AChE at the esteratic site and form an extremely stable enzyme-inhibitor complex that does not undergo significant spontaneous disassociation. The esteratic site is persistently phosphorylated, and recovery of cholinesterase activity is dependent upon *de novo* synthesis of new enzyme. Some organophosphates (e.g., echothiophate) may interact with both the anionic and esteratic sites. Because cholinesterase synthesis requires days, organophosphates cause an irreversible inhibition. As discussed below, however, certain oxime compounds exhibit such high affinity for the organophosphate that they can actually cause detachment of the inhibitor from the esteratic site, resulting in cholinesterase reactivation (see Fig. 7.8).

PHARMACOLOGIC EFFECTS. Effects of cholinesterase inhibitors can be reliably predicted by considering the anatomic location of cholinergic nerves and the respective physiologic processes they modulate in their innervated cells. Parasympathomimetic (muscarinic) effects of these agents are equivalent to the effects associated with postganglionic parasympathomimetic nerve impulses. Cholinesterase inhibitors also cause intensification of ACh activity at nicotinic sites. Therefore, these drugs can cause the following effects: stimulation of postganglionic muscarinic receptors of effector cells, resulting in typical parasympathomimetic activity; stimulation of adrenal chromaffin cells to discharge catecholamines into the circulation; initial stimulation and subsequent depolarization block of nicotinic receptors of autonomic ganglia and skeletal muscle fibers; and marked CNS cholinergic effects.

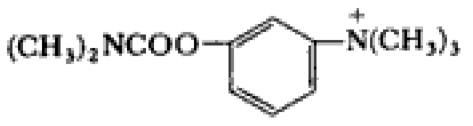
Although all these activities can be seen with excessive doses, therapeutic doses usually result in more selective actions; e.g., neostigmine and other quaternary nitrogen compounds do not easily penetrate the blood-brain barrier and therefore exert little CNS activity. These compounds are relatively more active at nicotinic receptors of the skeletal neuromuscular junction than at muscarinic sites of autonomic effector cells. Tertiary amines and organophosphates are less lipophobic and can cross the blood-brain barrier and evoke CNS effects. These compounds are relatively more active with low doses at autonomic receptor sites than on voluntary muscles.

Reversible Inhibitors. *Physostigmine,* USP (Eserine), is an alkaloid extracted from the dried ripe seed of a vine, *Physostigma venenosum,* which grows in tropical West Africa. This seed, also called the Calabar or "ordeal" bean, was used by tribal Africans in witchcraft ordeals. A person accused of a crime was forced to eat the bean. If vomiting occurred, the accused did not die and was considered innocent. If there was no vomiting, however, death resulted and the suspect was declared guilty.

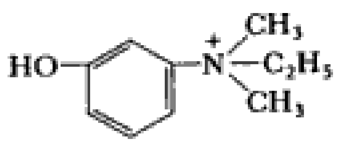
Neostigmine Bromide, USP (Prostigmine), is the salt of a synthetically produced substance discovered in a research investigation of compounds structurally related to physostigmine. Physostigmine also can be synthesized. *Edrophonium Chloride,* USP (Tensilon), is a synthetically derived agent that produces pharmacologic effects similar to neostigmine except that its duration of action is considerably shorter. It is used primarily as an anticurare agent. *Pyridostigmine Bromide,* USP (Mestinon, Regonol), and *Ambenonium Chloride,* USP (Mytelase, Mysuran), are moderately long acting, chemically synthesized cholinesterase inhibitors used primarily in management of myasthenia gravis and curare overdosage. The chemical structures of physostigmine, neostigmine, and edrophonium are shown in Fig. 7.6.



Physostigmine



Neostigmine



Edrophonium

FIG. 7.6

MECHANISM OF ACTION. These agents produce their effects by combining with cholinesterase and thereby preventing the enzyme from hydrolyzing ACh. ACh released during normal cholinergic nerve impulses has a prolonged and uninterrupted action upon cholinergic receptors. The interaction with cholinesterase is reversible, so as the inhibitor-enzyme complex breaks down, the enzyme is reactivated and it will now hydrolyze ACh and terminate its activity. At certain sites, neostigmine may act directly on receptors and evoke release of ACh from nerve endings; however, these are considered to be secondary actions.

PHARMACOLOGIC EFFECTS

DIGESTIVE TRACT. Physostigmine and neostigmine cause contraction of smooth muscle, thereby increasing motility and peristaltic movements of the gut. Frequency and strength of peristaltic waves are increased, and movement of intestinal contents is accelerated. Physostigmine has been used in animals for initiating peristaltic movements and evacuating the digestive tract. Excessive peristalsis leading to intestinal spasm and colic complicates use for this purpose. Physostigmine is given by SC or IM injection; its action after oral administration is unreliable. Neostigmine is not absorbed effectively after oral administration because of its quaternary nitrogen structure.

OCULAR EFFECTS. Physostigmine causes pupillary constriction and spasm of accommodation when applied locally to the eye or when injected for systemic effect. Intraocular pressure decreases, and physostigmine has been used in treating glaucoma to relieve elevated intraocular pressure.

SKELETAL MUSCLE. Besides its major action of inactivating AChE at the somatic myoneural junction, neostigmine is believed to directly stimulate nicotinic receptors of skeletal muscle fibers. Physostigmine is not active in denervated muscle. The skeletal muscle effects of neostigmine are relatively more pronounced at low doses than the smooth muscle effects of this agent. Twitching of skeletal muscles may be observed when a large dose of physostigmine or neostigmine is injected.

Physostigmine, neostigmine, pyridostigmine, and edrophonium are anticurare agents; they are antagonists to *d*-tubocurarine and other nondepolarizing (competitive) neuromuscular blocking agents at the somatic myoneural junction. These drugs can be used clinically to counteract an excessive dose of true curarimimetic agents but should not be used in attempts to antagonize the depolarizing neuromuscular blocking agents (e.g., succinylcholine), since synergism may actually occur (see Chap. 8).

OTHER EFFECTS. A therapeutic dose of physostigmine or neostigmine does not produce pronounced effects on cardiovascular function. Effects of higher doses are complicated by concurrent ganglionic stimulation and muscarinic effects on the heart and blood vessels. Usually, hypotension and a bradycardia leading to arrhythmias are produced. Smooth muscle of the bladder is cholinergically innervated and therefore is contracted by cholinesterase inhibitors. Bronchiolar smooth muscle is also contracted by these agents.

CLINICAL USES. *Physostigmine Salicylate*, USP (Isopto Eserine), or *Physostigmine Sulfate*, USP, can be used to produce miosis of the pupil and reduce intraocular pressure in the treatment of glaucoma. A solution of 0.5-1% physostigmine salicylate can be applied topically three times a day. The maximum miotic effect is obtained within an hour and may persist 12-24 hours, depending upon the dosage. Physostigmine may also be used alternately with atropine to prevent or break down synechia formed between lens and iris, such as occurs with periodic ophthalmia in horses.

Physostigmine has been used in a SC dose of 30-45 mg in cattle to stimulate ruminal activity in treatment of simple impaction or nonobstructive atony. Physostigmine, neostigmine, pyridostigmine, and edrophonium can be used to overcome the effects of true curare-like drugs in voluntary muscles, but the latter two agents are used more commonly for this purpose (Chap. 8).

Neostigmine has been used extensively in treating myasthenia gravis in humans. In myasthenia-like syndromes in dogs, neostigmine has also proved beneficial (Hall and Walker 1962). Marlow (1977) reported problems in controlling signs of myasthenia gravis in a dog treated with 60 mg neostigmine administered orally twice daily; difficulty was encountered in differentiating myasthenia crisis from cholinergic crisis. The former indicates an exacerbation of muscle weakness disease, whereas the latter refers to overdosage of the cholinesterase inhibitor with its attendant muscle weakness caused by excessive accumulation of ACh at the neuromuscular junction. Edrophonium, because of its brief duration of action, has been used to differentiate cholinergic and myasthenic crises in humans. If IV injection of this agent improves muscle function, myasthenia crisis is indicated and the dose of cholinesterase inhibitor used in maintenance therapy should be increased. However, if muscle weakness is accentuated by edrophonium, a cholinergic crisis is indicated and the dose of the cholinesterase inhibitor used in maintenance therapy should be reduced accordingly.

Impaction or other obstructions of the alimentary tract constitute a contraindication to the systemic use of cholinesterase inhibitors. Violent peristalsis produced by these drugs can cause rupture or intussusception of the gut. These drugs should not be used during pregnancy, particularly late in term, because of the danger of producing abortion.

TOXICOLOGY. Large doses of physostigmine first stimulate and then depress the CNS; small to moderate doses have little effect, whereas massive doses can produce convulsions. Neostigmine does not cross the blood-brain barrier to an appreciable extent. Toxic doses of these agents produce marked skeletal muscle weakness, nausea, vomiting, colic, and diarrhea. The pupil is markedly constricted and fixed. Dyspnea is characteristically seen from constriction of the bronchiolar musculature. Bradycardia and lowered blood pressure are also characteristic signs. Respiratory paralysis caused by depolarization block of the neuromuscular junction and compounded by excess bronchiolar secretions is the usual cause of death. Atropine is the most effective pharmacologic antagonist for physostigmine or neostigmine toxicity.

Organophosphorus Compounds. Diisopropyl fluorophosphate (diisopropyl phosphorofluoridate, DFP) is the prototypical organophosphate anticholinesterase agent. Related compounds include the alkyl pyrophosphates such as hexaethyltetraphosphate, tetraethylpyrophosphate (TEPP), and octamethyl pyrophosphortetramide (Taylor 1991). Organophosphates were

originally introduced as pesticides by German scientists prior to and during World War II; however, there was considerable speculation by many scientists as to the potential use of these highly toxic substances as antipersonnel devices in chemical warfare. Subsequently, a wide variety of organophosphorus compounds have been synthesized and extensively investigated. Some of the more important of these used as pesticides are parathion [Thiophos, diethyl *O*–(4-nitrophenyl) phosphorothioate]; malathion [*O,O*–dimethyl *S*–(1,2-dicarbethoxyethyl) phosphorodithioate]; ronnel [*O,O*–dimethyl *O*–(2,4,5-trichlorophenyl) phosphorothioate]; and Co-ral. Soman, tabun, and sarin are extremely potent synthetic compounds that have been referred to as nerve gases. Dichlorvos (*O,O*–dimethyl-2,2-dichlorovinyl phosphate or 2,2-dichlorovinyl dimethyl phosphate) has been used as an oral anthelmintic in veterinary medicine and impregnated in flea collars as a pesticide.

Although the chemical structures of organophosphate compounds vary considerably, the basic moiety is a phosphate with various organic groups attached to it, as described in Table 7.2. Representative structural formulas are shown in Fig. 7.7.

MECHANISM OF ACTION, EFFECTS, AND TOXICITY. Organophosphates act as irreversible inhibitors of the cholinesterases in mammals. These compounds irreversibly phosphorylate the esteratic site of both AChE and the nonspecific or pseudocholinesterase throughout the body (Fig. 7.8). Endogenous ACh is not inactivated, and the resulting effects are due to the excessive preservation and accumulation of endogenous ACh (Taylor 1990a, 1991; Gutman and Besser 1990). Organophosphate poisoning produces diffuse cholinomimetic effects: profuse salivation, vomiting, defecation, hypermotility of the GI tract, urination, bradycardia, hypotension, severe bronchoconstriction, and excess bronchial secretions. These signs reflect excess activation of muscarinic receptors of postganglionic parasympathetic neuroeffector junctions with typical parasympathomimetic actions.

In addition to the muscarinic effects, skeletal muscle fasciculations, twitching, and, subsequently, muscle paralysis occur. These effects are due to persistent excessive stimulation of the nicotinic receptors of skeletal neuromuscular junctions, resulting in the depolarizing type of striated muscle paralysis (Gutman and Besser 1990). Convulsions and frequently death are seen in organophosphate poisoning, caused by penetration of the agent into the CNS and subsequent intensification of the activity of ACh at CNS sites (Gutman and Besser 1990).

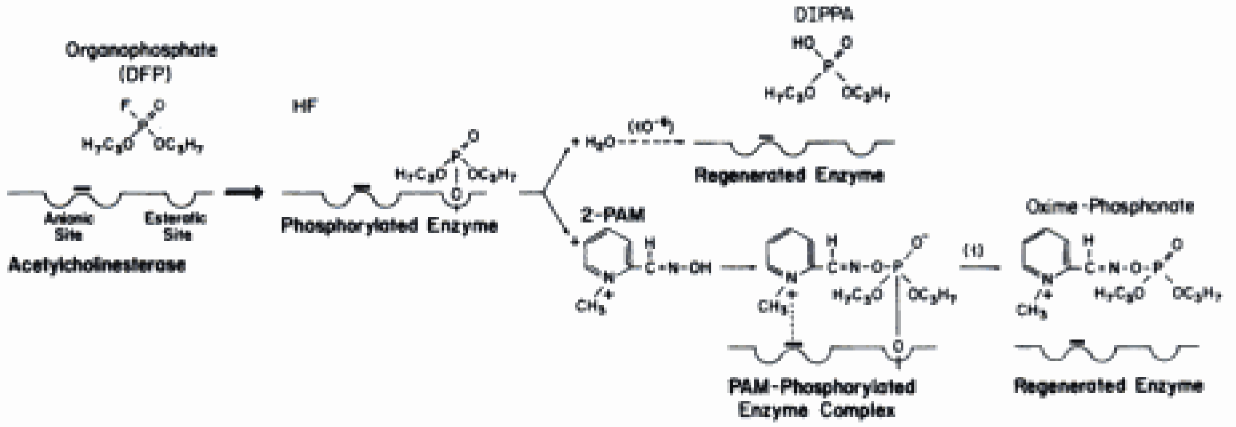

FIG. 7.8—Interaction of organophosphate diisopropyl fluorophosphate (DFP) with AChE and reversal by pralidoxime (2-PAM). DFP interacts irreversibly with the esteratic site of AChE to yield a phosphorylated enzyme complex with virtually no spontaneous release of diisopropylphosphoric acid (DIPPA) and regeneration of active enzyme. However, 2-PAM and other oximes can interact with the phosphorylated enzyme complex via electrostatic binding at the anionic site of AChE and binding at the P atom; the oxime-phosphonate is split off, yielding a regenerated enzyme. The numbers in parentheses refer to relative rates of reactions (Taylor 1990a; Inestrosa and Perelman 1990; Massoulie et al. 1993).

ANTAGONISTS AND ANTIDOTES

ATROPINE. Because atropine blocks muscarinic receptors, it not only lessens severity of the parasympathomimetic effects but also increases the quantity of organophosphate required to produce death; e.g., the ratio of the median lethal dose (LD_{50}) of sarin in atropine-treated dogs to the LD_{50} in nonatropinized dogs may be 150:1 (DeCandole and McPhail 1957). These ratios vary with the animal species and organophosphate, but atropine is almost invariably beneficial. In addition, because atropine is a competitive antagonist to ACh, large doses are effective even if administered after exposure to an organophosphate.

CHOLINESTERASE REACTIVATORS. Although phosphorylation of the esteratic site of cholinesterase by organophosphates yields a normally irreversible complex, certain compounds cause a disassociation of the enzyme bondage. Pralidoxime (pyridine-2-aldoxime-methiodide, 2-PAM) was synthesized based on structural requirements postulated by Wilson (1958) to be necessary for a selective antidote to organophosphate-cholinesterase interaction. This compound causes an effective removal of the phosphate group from the enzyme, so the enzyme is reactivated (Fig. 7.8). This and related oxime compounds are undoubtedly the most valuable adjunct to atropine therapy in treating organophosphate poisoning; e.g., pretreatment of animals with 2-PAM increases by several times the LD_{50} of various organophosphates. If atropine is given in conjunction with 2-PAM, the lethal dose is increased many more times.

Similarly, animals previously exposed to toxic doses of organophosphates experience considerable improvement after treatment with 2-PAM. In dogs, 10-20 mg/kg 2-PAM administered by slow IV injection is usually effective; this dose may have to be repeated. In horses and cattle, 20 mg/kg and 10-40 mg/kg respectively are used. Since 2-PAM significantly reverses the combination of organophosphate with cholinesterase, the reactivated enzyme can then perform its normal function. The phosphorylated enzyme complex tends to age with time and to become resistant to reactivation by oximes. Thus treatment with 2-PAM should not be delayed once organophosphate intoxication is diagnosed. Although treatment with 2-PAM alone has been used successfully in human incidences of organophosphate poisoning, atropine should always be used first to block muscarinic receptor sites.

Various other reactivator oximes such as pyridine-2-aldoxime dodecaiodide (designed for CNS effects), monoisonitrosoacetone, and diacetylmonoxime have also been investigated. Oxime reactivators are probably ineffective in antagonizing the carbamate cholinesterase inhibitors and in some cases apparently can act synergistically.

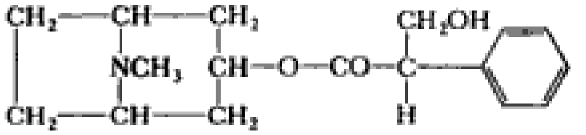
CLINICAL USES OF ORGANOPHOSPHATES. Organophosphorus compounds have achieved widespread use as anthelmintics and pesticides because they are highly toxic to a wide variety of internal and external parasites. Their introduction in the late 1940s and 1950s had considerable impact on pest control. Concurrent with their widespread use, however, is the potential for immediate and/or delayed damage to humans, domestic animals, and wildlife. The ecologic impact of organophosphate pesticides has received considerable attention from various conservation organizations, and there is some evidence that certain of the compounds may be tumorigenic when given in large doses to experimental animals. Dichlorvos-impregnated collars can occasionally cause hypersensitivity skin reactions on the animal's neck and, less frequently, on pet owners.

Organophosphates such as DFP and TEPP have been used locally to constrict the pupil in human patients for treatment of glaucoma; DFP (0.1% in peanut oil) and echothiophate (phospholine iodide, 0.03-0.25% solutions) are sometimes used for this purpose in dogs. Effects of these compounds are relatively long lasting and the dosage must be carefully controlled.

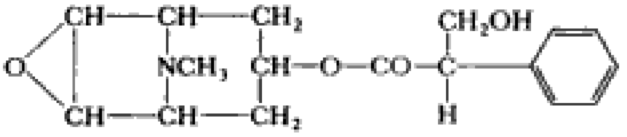
PRECAUTIONARY NOTE ABOUT CLINICAL USES OF CHOLINESTERASE INHIBITORS. As repeatedly emphasized, cholinesterase inhibitors are highly reactive molecules capable of influencing functions of cholinergic nerves throughout the body. This is particularly true with the organophosphates. At no time should their clinical use be considered as an innocuous procedure. Care should always be taken by the clinician to insure that the patient is not exposed either to drugs that are metabolized by cholinesterase (e.g., succinylcholine) or to other cholinesterase inhibitors (e.g., pesticide dips or sprays) for several days before and after administering either a reversible or irreversible anticholinesterase agent. If not, serious and even fatal synergistic interactions can occur (Hines et al. 1967). Other types of drugs (e.g., phenothiazine tranquilizers) may decrease cholinesterase activity as a potential side effect; their concurrent use with anticholinesterase drugs should be avoided or closely monitored.

Severely ill, debilitated animals should not be exposed to a cholinesterase inhibitor except in emergency situations. If hepatic disease is presented, synthesis of cholinesterase may be markedly reduced and effects of cholinesterase inhibitors can be intensified and/or prolonged. Respiratory illness may be exacerbated by excessive bronchiolar constriction and secretion. Abortion may occur, particularly during the latter gestational periods. Because of the potency of cholinesterase inhibitors, especially organophosphate compounds, care should always be taken to closely follow the manufacturer's individual dosage recommendations and procedural directions.

PARASYMPATHOLYTIC AGENTS. Parasympatholytic drugs prevent ACh from producing its characteristic effects in structures innervated by postganglionic parasympathetic nerves. They also inhibit effects of ACh on smooth muscle cells that respond to ACh but lack cholinergic innervation; i.e., these drugs inhibit the muscarinic actions of ACh and related cholinergic agonists. In fact, "muscarinic blocking" or "antimuscarinic" is actually more completely descriptive of the effects of this group of drugs than is "parasympatholytic," because muscarinic receptors are blocked irrespective of whether they are innervated by a parasympathetic nerve. Clinically, however, these drugs are used almost exclusively for their parasympatholytic activities. This group of drugs includes atropine and related alkaloids and numerous synthetically derived compounds.



Atropine



Scopolamine

FIG. 7.9

Atropine and Scopolamine. Atropine, the prototypical muscarinic blocking agent, is an alkaloid extracted from the belladonna plants that belong to the Solanaceae (potato family) and include *Atropa belladonna* (deadly nightshade), *Datura stramonium* (jimsonweed), and *Hyoscyamus niger* (henbane). Alkaloids obtained from *Atropa belladonna* are atropine (which is a racemic mixture of *d*-hyoscyamine and *l*-hyoscyamine, racemization occurring during the extraction procedure), scopolamine (*l*-hyoscine), and others of lesser significance. Because atropine is actually an equal mixture of *d*- and *l*-hyoscyamine and the dextro form of hyoscyamine is biologically inactive, a given quantity of atropine is about one-half as potent as the same quantity of *l*-hyoscyamine. Despite the inactive dextrorotatory component, atropine is nevertheless effective in very small doses. Chemically, the atropine molecule consists of two components joined through an ester linkage: tropine, which is an organic base, and tropic acid. Other related alkaloids also contain the aromatic tropic acid moiety combined by ester linkage to either tropine or another organic base, scopine. The chemical structures of atropine and scopolamine are given in Fig. 7.9.

MECHANISM OF ACTION. *Atropine Sulfate*, USP, *Scopolamine Hydrobromide*, USP (Hyoscine), and other related alkaloids interact with muscarinic receptors of effector cells and by occupying these sites prevent ACh from affixing to the receptor area. Physiologic responses to parasympathetic nerve impulses are thereby attenuated. Pharmacologic effects of exogenously administered ACh and other muscarinic agonists are similarly blocked by atropine and scopolamine. Although muscarinic receptors have been divided into M_1, M_2, M_3 and perhaps other subtypes (Chassaing et al. 1984; Brown 1990), the utility of this nomenclature to clinical veterinary medicine is unclear at this time.

Blockade of muscarinic receptors of smooth muscle, cardiac muscle, and glands by atropine-like drugs involves a competitive antagonism. Therefore, large doses of ACh or other cholinomimetic drugs (e.g., carbachol, cholinesterase inhibitors) can overcome or surmount inhibitory effects of atropine at these sites.

Although atropine and related compounds act immediately distal to all postganglionic cholinergic nerve endings, this block is not equally effective throughout the body. Salivary and cholinergic sweat glands are quite susceptible to small doses of atropine, whereas somewhat larger doses are required for a vagolytic effect upon the heart. GI and urinary tract smooth muscles are less sensitive to atropine, and even larger dosages are required to inhibit gastric secretion. Except for effects on salivation and cholinergic sweating, it is difficult to achieve a selective action on targeted structures without concurrently inducing side effects on other, more susceptible sites. Net pharmacologic effects of atropinic drugs in a particular organ are influenced by the relative dominance of parasympathetic or sympathetic tone in that structure. After cholinergic impulses are blocked, adrenergic nerves become dominant and sympathomimetic-like effects may contribute to the final effect.

PHARMACOLOGIC EFFECTS

CARDIOVASCULAR SYSTEM. The usual therapeutic doses of atropine do not markedly affect blood pressure; however, pulse rate is altered. Tachycardia is the dominant effect, and large doses of atropine invariably produce an increased heart rate. Small doses may initially produce a slight slowing of heart rate, but this effect is believed to be due to transient stimulation of vagal nuclei of the medulla oblongata and perhaps to transient stimulation of peripheral receptors prior to their block (Averill and Lamb 1959; Ashford et al. 1962). The ease with which atropine produces tachycardia is dependent in part upon the degree of vagal tone of the individual patient. Because atropine blocks transmission of vagal impulses to the heart, animals with a preexisting high vagal tone would show a relatively greater tachycardia than those with low vagal tone.

Cardiac output tends to increase with atropine primarily because of increase in heart rate. Arterial blood pressure either remains unchanged or increases slightly in a normal animal. In animals exposed to exogenous ACh or other cholinomimetics (e.g., cholinesterase inhibitors), atropine can cause a relative increase in blood pressure, because muscarinic effects of the agonists will be blocked. Also, atropine unmasks the hypertensive response to high experimental doses of cholinergic agonists resulting from their nicotinic effects (see Fig. 7.3).

Because atropine blocks the cardiac vagus, it markedly reduces or abolishes cardiac inhibitory effects of drugs acting through a vagal mechanism and will attenuate vagal-mediated reflex responses. Accordingly, the pressor effects of epinephrine and norepinephrine are accentuated in atropinized animals by blockade of the cardiac limb of vagal-baroreceptor reflexes. Large doses of atropine are directly depressant to the myocardium and also cause cutaneous dilation as a result of a direct vascular smooth muscle effect.

GI SYSTEM. Atropine causes relaxation of GI smooth muscle by inhibiting contractile effects of cholinergic nerve impulses. Thus, atropine and related drugs can be helpful in treatment of intestinal spasm and hypermotility. Inhibition of smooth muscle motility extends from stomach to colon, although the degree of blockade may not be uniform. Insofar as rumen motility is concerned, adequate doses are consistently inhibitory, and atropine is one of the few agents that can be relied upon to produce cessation of rumen motility.

Secretions of the GI tract are also blocked by atropine. Salivation is reduced quite markedly. Similarly, secretions of intestinal mucosa are inhibited; however, gastric secretions are reduced only with exceedingly high doses that also block virtually all other muscarinic sites.

BRONCHIOLES. Cholinergic innervation to the bronchioles modulates secretion of mucus and contraction of bronchiolar smooth muscle. Atropine and other drugs of the belladonna group block effects of cholinergic impulses and thereby decrease secretions and increase luminal diameter of the bronchioles. The dilator action of atropine is valuable in counteracting constriction of bronchioles following overdosage of a parasympathomimetic drug.

Atropine often will give temporary symptomatic relief from the dyspnea of "heaves" in horses, and it has been used by unscrupulous individuals for this purpose. A SC dose of atropine (30 mg) may produce immediate relief in the horse lasting 1-3 hours; however, dyspnea worsens after effect of the drug has terminated. A crude form of the drug, such as belladonna leaves, administered orally produces its effect within 30 minutes, with a duration of about 24 hours. When atropine medication is suspected, the following signs should be detectable: dry oral mucosa, dilated and relatively fixed pupils, and tachycardia.

OCULAR EFFECTS. Atropine blocks the cholinergically innervated sphincter muscle of the iris and the ciliary muscle of the lens, resulting in mydriasis and cycloplegia after topical or systemic administration. Because atropine blocks cholinergic effects, adrenergic nerve impulses dominate and the pupil actively dilates. Atropine is contraindicated in the presence of increased intraocular pressure from acute angle glaucoma because the drainage system of the anterior chamber of the eye is impeded during mydriasis.

URINARY TRACT. Atropine relaxes smooth muscle of the urinary tract. The spasmolytic effect on the ureters may be of some benefit in treatment of renal colic. Atropine tends to cause urine retention because it inhibits smooth muscle tone. This effect may be of some use in reducing frequency of micturition that accompanies cystitis; however, the deleterious effects of only partially emptying the bladder should be considered.

SWEAT GLANDS. Atropine has a definite anhydrotic action in species such as humans, who have a cholinergic mechanism in control of sweat secretion, and a large dose may cause a hyperpyrexic response. Atropine does not directly affect sweating in species that have adrenergic mechanisms in control of sweating (e.g., equines) and has minimal effect in species that do not use cholinergic sweating as an important component of thermoregulation.

CENTRAL NERVOUS SYSTEM. Therapeutic doses of atropine produce minimal effects on the CNS. Excessive doses may cause hallucinations and disorientation in humans and mania and excitement in domestic animals. Excessive motor activity followed by depression and coma is the usual sequence of events. Scopolamine has a slight sedative effect; when combined with morphine it produces analgesia and amnesia (referred to as "twilight sleep") in human patients. These effects of scopolamine usually are not detectable in domestic animals. While small doses may be depressant in dogs and cats, larger doses produce delirium and excitement in these species and also in horses.

TOXICOLOGY. There is considerable interspecies variation in the toxicity of belladonna and atropine; the route of administration is also important. Herbivora are usually more resistant than Carnivora. Certain strains of rabbits are quite resistant to a diet of belladonna leaves, because an esterase (atropinase) of the liver hydrolyzes and thus inactivates atropine. However, rabbits fed on such a diet may prove toxic if eaten by dogs, cats, or humans because of the large amount of alkaloid present in muscle tissues. Horses, cattle, and goats are relatively resistant to belladonna when it is administered orally; however, these species are quite susceptible to atropine when it is injected parenterally. Swine are not resistant to belladonna ingested from eating the deadly nightshade plant.

Signs of atropine poisoning are similar in all mammalian species. Dry mouth, thirst, dysphagia, constipation, mydriasis, tachycardia, hyperpnea, restlessness, delirium, ataxia, and muscle trembling may be observed; convulsions, respiratory depression, and respiratory failure lead to death. A drop of urine obtained from a patient suspected of atropine toxicosis causes mydriasis when placed in the eye of a cat. Also, the tested pupil will not constrict when exposed to light, while the untreated eye will. This simple procedure may prove helpful in the differential diagnosis of belladonna intoxication.

CLINICAL USES. Parasympatholytic drugs are used to control smooth muscle spasm as antispasmodics or spasmolytics. Antispasmodics can be used to decrease or abolish GI hypermotility and depress hypertonicity of the uterus, urinary bladder, ureter, bile duct, and bronchioles. Parasympatholytics are not as effective as epinephrine or other adrenergic amines in dilating the bronchioles, but atropine is effective in antagonizing excessive cholinergic stimulation at these sites.

Atropine is used routinely as an adjunct to general anesthesia, particularly with inhalant anesthetics, to decrease salivary and airway secretions. Also, atropine is frequently given in conjunction with morphine to reduce salivary secretions that may be produced by the latter drug. When used prior to anesthesia, the dose of atropine in dogs is 0.045 mg/kg, administered subcutaneously.

The newer inhalant anesthetics produce minimal respiratory irritation, and bronchiolar secretions are considerably less pronounced than with older agents like ether. Thus the routine preoperative use of atropine in all patients has been questioned, especially because this drug may increase the potential for certain cardiac arrhythmias. Moreover, use of atropine in cattle often results in several days of inappetence concomitant with postoperative rumen stasis (Garner et al. 1975). In the horse, use of atropine is sometimes questioned because of the possibility of reducing intestinal motility to the degree that colic develops (Klavano 1975). However, some clinicians cautiously use IV atropine (0.01 mg/kg) to prevent the second degree heart block induced by xylazine in horses. Because of the incidence or potential for anesthesia-associated tachyarrhythmias with atropine, glycopyrrolate (see below) has been advocated as an alternative to atropine for muscarinic blockade in routine preanesthetic medication.

Atropine is used routinely to facilitate ophthalmoscopic examination of internal ocular structures and functions and also for treatment of various ocular disorders. Homatropine hydrobromide, because of its shorter duration of action, has largely replaced atropine for ophthalmoscopic purposes in human patients. Application of a few drops of 1-2% solution of atropine into the conjunctival sac causes mydriasis within 15-20 minutes. Maximum pupillary dilation occurs in about 2 hours and may be detectable for several days. The time course of the cycloplegic action of atropine is similar to that of mydriatic action. Mydriatics like atropine are helpful in preventing or breaking down adhesions between the iris and the lens when used alternately with miotics.

Atropine is an essential antidote to anticholinesterase overdosage or poisoning.

Synthetic Muscarinic Blocking Agents. Synthetic muscarinic blocking agents were chemically synthesized in attempts to find atropine substitutes that would act selectively at certain muscarinic sites and therefore would have fewer undesirable side effects than the alkaloids.

GLYCOPYRROLATE. *Glycopyrrolate,* NF, is a quaternary nitrogen anticholinergic agent that has received attention for preanesthetic use in veterinary medicine.

It exerts potent antimuscarinic activity but reportedly has some benefits when compared to atropine. The tachycardia response associated with muscarinic block at the SA node, e.g., seems to be somewhat less of a problem with glycopyrrolate. In dogs this compound effectively diminishes the volume and acidity of gastric secretions and reduces intestinal motility; it also reduces and controls excessive secretions of the respiratory tract. Similar control of respiratory secretions by glycopyrrolate has been reported in cats, and its duration of action exceeds that of atropine. Also, because of its more polar nitrogen moiety, glycopyrrolate penetrates the blood-brain barrier less effectively than atropine, with less propensity for unwanted CNS side effects. The muscarinic blocking action of glycopyrrolate is evident within minutes after IV injection. After SC or IM administration, maximal effects generally develop within 30-45 minutes, and vagal blocking action can be demonstrated for 2-3 hours, while the antisialagogue response is evident for up to 7 hours. The glycopyrrolate dose is approximately 10 µg/kg by SC, IM, or IV routes, administered 15 minutes or so prior to anesthetic induction (Short et al. 1974; Short and Miller 1978).

HOMATROPINE. *Homatropine Hydrobromide,* USP, is similar in structure to atropine except that it is an ester of mandelic acid rather than of tropic acid. Homatropine closely resembles atropine in most of its pharmacologic actions, particularly the ocular effects. Mydriasis and cycloplegia are produced in the eye by topical application of a 2-5% solution of homatropine, but these effects last for a shorter duration than those resulting from atropine. Homatropine produces fewer side effects on cardiovascular and GI functions than atropine and is considerably less toxic than the parent drug.

METHANTHELINE, PROPANTHELINE, AND METHYLATROPINE. *Methantheline Bromide,* USP, *Propantheline Bromide,* USP, and *Methylatropine Nitrate,* INN, are quaternary amines used primarily as smooth muscle relaxants. Because of the charged quaternary group, these compounds do not cross the blood-brain barrier to an appreciable extent. Accordingly, they are considerably less effective than atropine as antagonists to organophosphates, since the CNS effects of the latter agents would not be blocked. In addition to muscarinic blocking effects, these drugs act as autonomic ganglionic blockers, which most likely contributes to their antispasmodic effect on GI smooth muscle.

AUTONOMIC GANGLIONIC BLOCKING DRUGS

Mechanisms. Following Langley's investigations in 1889, it has been known that small doses of nicotine stimulate autonomic ganglion cells, and larger doses block the transmitter function of ACh at these same sites. Therefore, the cholinergic receptors of ganglion neurons have been classified as nicotinic. Considerable evidence is now available indicating that impulse transmission within autonomic ganglia is much more complicated than originally believed. Studies have demonstrated a secondary excitatory cholinergic pathway in autonomic ganglia that is apparently muscarinic, and an inhibitory catecholaminergic mechanism has also been recorded (Eccles and Libet 1961; Libet 1970; Akasu 1992). The different putative pathways involved in synaptic transmission in sympathetic autonomic ganglia are shown schematically in Fig. 7.10.

The physiologic purposes of these different ganglionic pathways are poorly understood. Evidence for participation of different types of receptors has been gained primarily from studies of sympathetic ganglia. Parasympathetic ganglia are studied less frequently because of their poor accessibility. The nicotinic receptor represents the primary ganglionic transmission pathway present in all autonomic ganglia. The muscarinic receptors on the postganglionic neuron may facilitate impulse transmission events that are normally dominated by the nicotinic mechanisms. The adrenergic component may act as a modulator to prevent excessive impulse traffic.

Nicotine. Nicotine is an alkaloid obtained from leaves of the tobacco plant. Nicotine sulfate, the most commonly produced salt, is available commercially in an aqueous solution that contains 40% alkaloidal nicotine. This solution long has been designated by the proprietary name of Blackleaf 40. Nicotine was the original autonomic ganglionic blocking agent; however, it is not used clinically for this purpose. Nicotine first stimulates and then in higher doses blocks nicotinic receptors by producing a persistent depolarization of the receptor area.

PHARMACOLOGIC EFFECTS

CENTRAL NERVOUS SYSTEM. Alkaloidal nicotine is an extremely toxic substance that transiently stimulates and then severely depresses the CNS. Death is from respiratory paralysis of the diaphragm and chest muscles resulting from descending paralysis and depolarization block of the nerve-muscle junction of skeletal muscle. Nicotine is absorbed through the chitinous shell of insects after a direct spraying or after contacting a sprayed surface and kills by paralysis of the CNS.

CARDIOVASCULAR SYSTEM. Both cardioaccelerator and cardioinhibitor nerves are activated by small amounts of nicotine, which cause stimulation of all autonomic ganglia. Since the cardioinhibitor nerve (vagus) is predominant, the response to a small dose, or the initial response to a large dose, of nicotine is a decreased pulse rate. Because of paralysis of all autonomic ganglia, the heart rate returns toward normal after a large dose has taken full effect, and a relative

FIG. 7.10—Impulse transmission in sympathetic autonomic ganglia. ACh is discharged from the preganglionic nerve terminal and interacts with a nicotinic receptor on the ganglionic neuron to cause a rapid depolarization measured electrically as a fast excitatory postsynaptic potential (EPSP). ACh also interacts with a muscarinic receptor on the ganglionic neuron to cause a delayed depolarization measured electrically as a slow EPSP. In addition, ACh activates nearby chromaffin cells through a muscarinic receptor, which results in a release of catecholamine (CA: dopamine or epinephrine). CA interacts with an α receptor on the ganglionic neuron to cause an inhibitory (hyperpolarization) response measured electrically as an inhibitory postsynaptic potential (IPSP). 1° and 2° indicate primary (nicotinic) and secondary (muscarinic) pathways of excitatory ganglionic impulses respectively; hex = hexamethonium (Eccles and Libet 1961; Libet 1970; Nishi 1974; Akasu 1992).

tachycardia may result. Similarly, small doses of nicotine can cause a pressor response, by stimulation of the predominating sympathetic ganglia that furnish postganglionic vasoconstrictor fibers to arterioles. However, peripheral vasodilation results from ganglionic block after large doses.

GASTROINTESTINAL. Nicotine activates the smooth muscles and secretory glands of the digestive tract with the following clinical signs: excessive salivation, increased gastric secretion, vomiting, increased peristalsis, and defecation.

SKELETAL MUSCLE. Nicotine initially stimulates nicotinic receptors of the motor end-plate and in large doses produces a depolarizing muscle paralysis. This effect has been used in attempts to immobilize wild animals for capture.

ACUTE NICOTINE POISONING. Accidental ingestion of the 40% solution of nicotine sulfate results in acute toxicosis characterized by excitement, hyperpnea, salivation, pulse rate irregularities, diarrhea, and emesis in species that vomit. After this transient stimulatory phase, a depressed state occurs and is characterized by incoordination, tachycardia, dyspnea, coma, and death from respiratory paralysis.

Synthetic Ganglionic Blocking Agents. Nicotine is not used clinically in animals or humans as a ganglion blocker, since it activates nicotinic sites before blockage occurs and affects functions of various tissues throughout the body. However, several drugs have been discovered that preferentially block autonomic ganglia by a nondepolarizing (competitive) mechanism. These drugs are bis-quaternary compounds, i.e.,

$$(\mathrm{CH3})_3\overset{+}{\mathrm{N}}(\mathrm{CH}_2)_4\overset{+}{\mathrm{N}}(\mathrm{CH}_3)_3$$

In cases where the methonium groups are separated by 5 or 6 methylene groups (i.e., *n* = 5 or 6), a selective site of action at autonomic ganglia is obtained. These compounds interact with nicotinic receptors of the ganglion cells and thereby block impulse transmission across the ganglionic synapse. Dissimilar to nicotine, they do not cause initial depolarization. Members of this group of ganglionic blocking agents include hexamethonium (*n* = 6; *C*-6), pentamethonium (*n* = 5; *C*-5), chlorisondamine, pentolinium, trimethidinium, and azamethonium. In addition, there are several other ganglionic blocking drugs that are not bis-quaternary compounds, such as tetraethylammonium ions, mecamylamine, and pempidine.

PHARMACOLOGIC EFFECTS AND USES. Because of the blockade of impulse transmission at the ganglia, effects of ganglionic blocking agents are manifested on effector organs innervated by the postganglionic fibers of the sympathetic or parasympathetic nervous system. The overall effects of these agents on various functions are dependent upon the predominance of sympathetic or parasympathetic tone in a particular structure, as indicated in Table 7.3 (Taylor 1990b). Because the GI system functions predominantly under parasympathetic tone, ganglionic blockade will result in a relative parasympatholytic effect; decreased motility and secre-

TABLE 7.3—Usual predominance of sympathetic or parasympathetic tone in various tissues and consequent effects of autonomic ganglionic blockade

Structures	Predominant tone	Effects of ganglionic blockade
Cardiovascular		Overall depression; block reflexogenic changes
Arterioles	Sympathetic	Vasodilation: increased peripheral blood flow; hypotension
Veins	Sympathetic	Vasodilation: pooling of blood; decreased venous return
Heart	Parasympathetic	Tachycardia
Gastrointestinal	Parasympathetic	Decreased tone and motility; constipation
Eye		
Iris	Parasympathetic	Mydriasis
Ciliary muscle	Parasympathetic	Cycloplegia
Urinary bladder	Parasympathetic	Urinary retention
Salivary glands	Parasympathetic	Dry mouth
Sweat glands	Sympathetic	Annidrosis

tions and constipation result. Similarly, because heart rate is under dominant vagal tone, a relative tachycardia may result. However, because tone of peripheral blood vessels is dominated by sympathetic impulses, vasodilation and hypotension occur after ganglionic block. Similarly, the output of catecholamines by the adrenal medulla is also reduced. Severe postural hypotension and even syncope may result. The hypotensive effect has occasionally been utilized in surgery to decrease the chance of hemorrhage in highly vascular areas; however, ganglionic blocking agents have achieved no significant purpose in clinical veterinary medicine.

Numerous drugs have been identified that inhibit transmission of nerve impulses at the somatic neuromuscular junction. Neuromuscular blocking agents used clinically act by interfering with the effectiveness of the endogenous neurotransmitter acetylcholine (ACh) to activate nicotinic cholinergic receptors of skeletal muscle cells. The end results of this action are skeletal muscle paralysis and muscular relaxation. Neuromuscular blocking agents are most often used as adjuvants to anesthesia to facilitate tracheal intubation, abdominal muscle relaxation, and orthopedic manipulations, and as part of balanced anesthesia procedures to reduce the amount of general anesthetic required.

DEVELOPMENT. Development of neuromuscular blocking drugs originated with the discovery of curare, a tarlike mixture of plant material used as a poison by South American Indians. The actual ingredients of the poison for arrows, blowgun darts, and spears were known only to the local "pharmacist," who was often the tribal medicine man or witch doctor. Thus the botanical preparations obtained by explorers could not be identified as to content; they were simply classified according to the containers in which they were packaged. Tubo-, para-, or bamboo-curare was contained in cutoff bamboo tubes; this mixture was usually obtained from southern Amazon tribes. The plant origin of tube-curare preparations was primarily Menispermaceae (*Chondodendron tomentosum*). Calabash-curare was packaged in hollow gourds or calabashes; it was the most active preparation. Pot-curare came in small earthenware pottery from the central part of the Amazon basin; this concoction often contained plants other than Menispermaceae. The most important constituent isolated from curare is *d*-tubocurarine. Complete discussions of the colorful and interesting history of curare have been presented by McIntyre (1972) and Waser (1972).

Original studies in the nineteenth century by Claude Bernard (1856) demonstrated that curare prevented the muscle contraction elicited by stimulation of the motor nerve. It did not, however, affect the central nervous system (CNS), prevent response to direct stimulation of the muscle, or depress axonal conductance. It was proposed that curare acted at the nerve-muscle junction. Reports since then have substantiated, clarified, and extended observations concerning the neuromuscular blocking properties of curare alkaloids. Early results stimulated active research into the chemical structural requirements of curare-like compounds, leading to the discovery of other types of neuromuscular blocking agents.

THE NICOTINIC RECEPTOR AND STRUCTURE-ACTIVITY RELATIONSHIPS. Neuromuscular blocking agents possess chemical structural groups that allow interaction of the agent with the nicotinic cholinergic receptor. However, these drugs cause distinctly different effects from the endogenous mediator ACh. One group of neuromuscular blocking drugs, competitive agents, occupies the receptor so that ACh cannot act. The other group, depolarizing agents, acts in a more complicated manner and initially causes depolarization before blockage occurs.

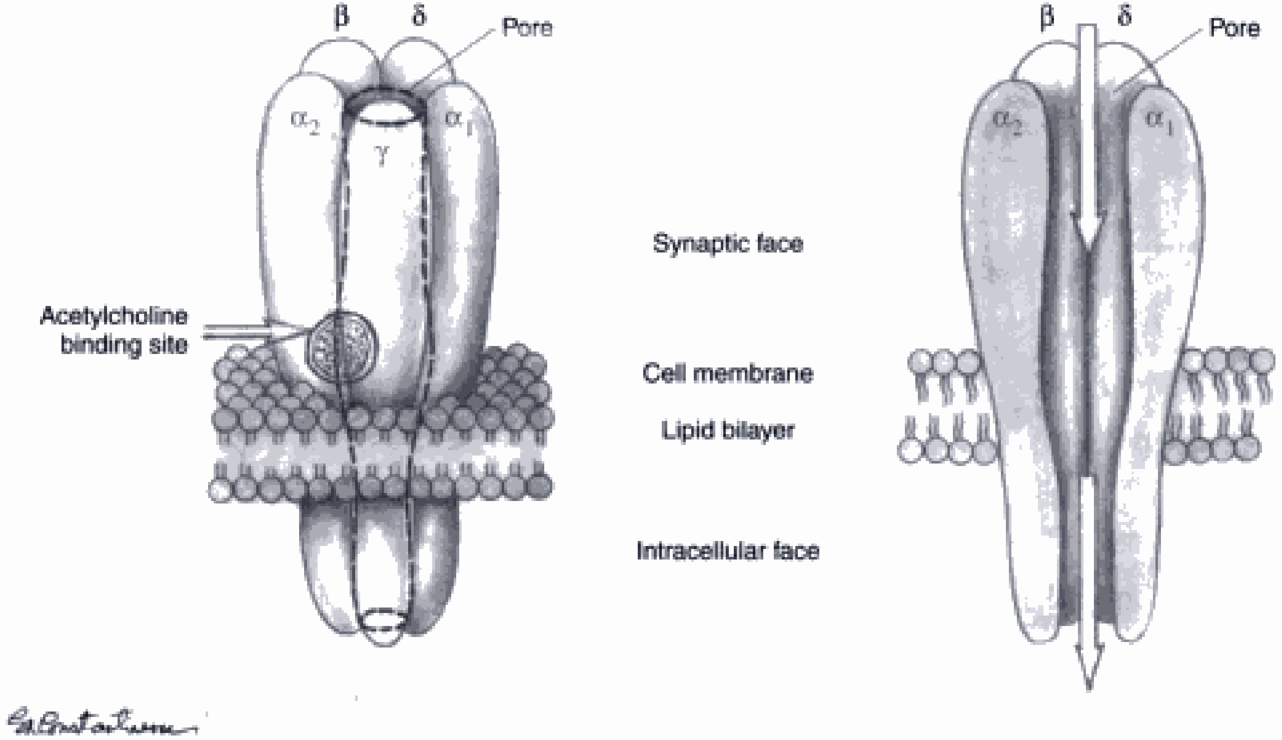

FIG. 8.1—Schematic representation of the nicotinic cholinergic receptor. The receptor is embedded across the cell membrane lipid bylayer, presenting a synaptic face to the neuroeffector junction between the neuron and innervated cell, and an intracellular face within the cytoplasm. The receptor comprises a pentameric configuration of four separate subunits with a stoichiometric ratio of $\alpha_2\beta\gamma\delta$; in adult muscle $\alpha_2\beta\epsilon\delta$. The α subunits contain the primary ligand binding sites for recognition of acetylcholine and related agents. Subunit arrangement forms an internal pore that allows passage of select ions upon receptor activation and resulting membrane depolarization (see text). Redrawn from Unwin et al. (1988) by Dr. Gheorghe M. Constantinescu, University of Missouri.

Based on general chemical structural characteristics, Bovet (1951) placed neuromuscular blocking agents into two large categories. One group is characterized by large, bulky, and nonflexible molecules; members of this group include *d*-tubocurarine, dimethyl (or trimethyl) tubocurarine, gallamine, and pancuronium, all of which produce a competitive (nondepolarizing) block. The other group is characterized by long, slender, flexible molecules that allow free bond rotation. Decamethonium and succinylcholine are in this group; these agents cause a depolarizing block. The dichotomy in basic structural arrangement of competitive and depolarizing agents has been offered as a partial explanation for dissimilar effects evoked by interaction of these agents with the nicotinic cholinergic receptor.

The proposed charge distribution of the cholinergic receptor was shown in Chap. 7, and a schematic of the nicotinic cholinergic receptor is illustrated in Fig. 8.1. Among other requirements, receptors contain anionic (negatively charged) binding sites separated by set distances. These negative sites are essential for electrostatic bonding of the cationic (positively charged) nitrogen moiety of ACh (and exogenous chemicals) to the receptors.

Occupation of negative binding sites by ACh activates influx of Na^+ and efflux of K^+ along their respective concentration gradients, resulting in membrane excitation. Occupation of these sites by the molecularly rigid competitive agents stabilizes the receptors so that the membrane pores are not easily affected. Depolarizing agents initially act similarly to ACh. Because of their flexible structure, they allow initial channel activation but for some reason cause a persistent short-circuiting of the receptor so that additional changes in electrical potential are not achieved.

Different investigative groups have now isolated the nicotinic cholinergic receptor from the electric eel and electric ray (Taylor 1990a,b; Unwin et al. 1988) and also from mammalian skeletal muscle (Dolly and Barnard 1977). The cobra neurotoxin, α-bungarotoxin, binds irreversibly and with high specificity to ligand recognition sites of the nicotinic receptor. This toxin, when radiolabeled, has allowed remarkable achievements in isolating and characterizing the nicotinic receptor (Kistler et al. 1982).

The nicotinic cholinoceptor is a pentameric asymmetric molecule (8 × 14 nm) of about 250 kilodaltons that spans the bilayer of the postjunctional membrane (Fig. 8.1). The receptor comprises five individual subunits in a stoichiometric ratio of $\alpha_2\beta\gamma\delta$; the γ-subunit is replaced by an ε-subunit in muscle from adult animals. Each subunit has an extracellular and intracellular

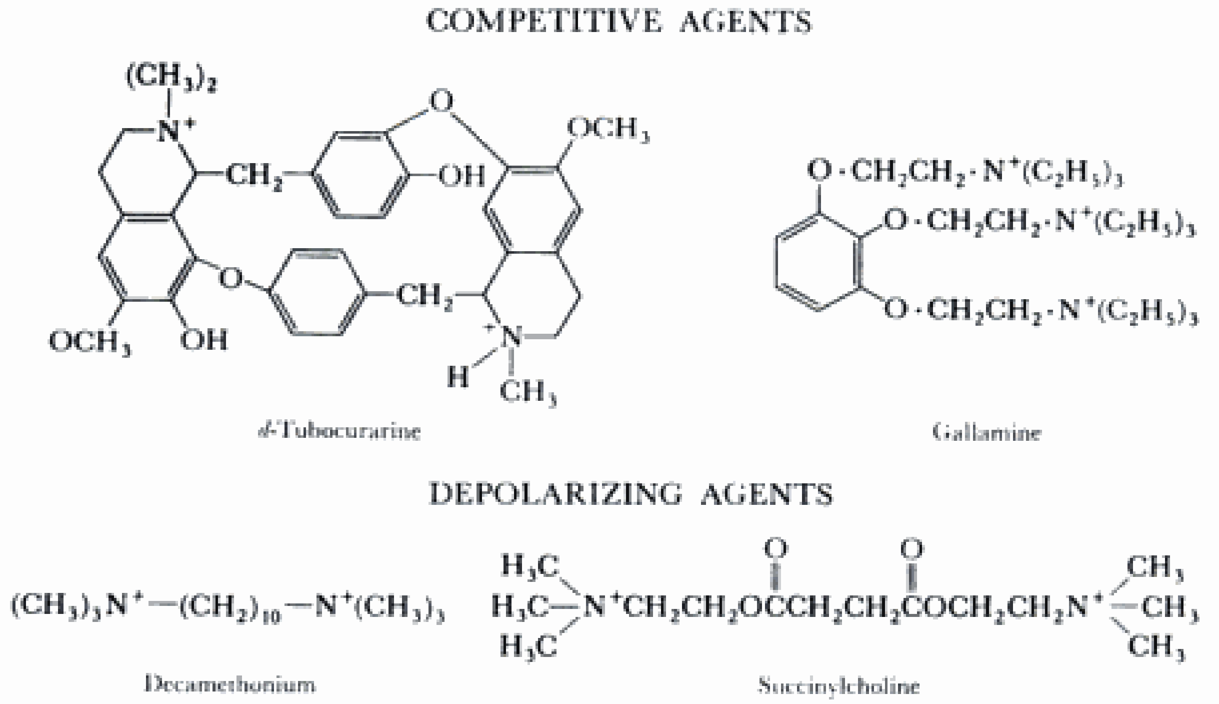

FIG. 8.2—Chemical structures of some commonly used neuromuscular blocking agents.

exposure and also contains sequences of hydrophobic amino acids that are the likely regions embedded within the membrane bilayer (Taylor 1990b). In vivo, the pentamerous receptor complex occurs as a dimer or couplet, with two adjacent receptors connected via a disulfide bond between two δ-subunits. The five subunits of each monomere receptor complex are elongated perpendicular to the postjunctional membrane and are arranged circumferentially to form a rosette around a central lumen (Fig. 8.1). This central transmembrane channel of the receptor complex represents the previously discussed membrane pore for ion fluxes instigated by agonist activation of the receptor. Agonist and antagonist binding sites are believed to be restricted to the α-subunits (Kistler et al. 1982). Whereas acetylcholine evokes receptor activation upon binding to the α-subunits, occupation of these same sites by antagonists prevents effective receptor activation. The muscle becomes paralyzed, whether in response to a competitive blocking agent or to transient activation by a depolarizing blocking agent.

Chemical structures of several commonly used neuromuscular blocking agents are shown in Fig. 8.2 to demonstrate structural differences of the competitive and depolarizing types.

IMPULSE TRANSMISSION AT THE SOMATIC NEUROMUSCULAR JUNCTION. Prior to discussing neuromuscular blocking agents, impulse transmission at the somatic neuromuscular junction will be reviewed in relation to sites of action of different drugs. General concepts of cholinergic transmission were mentioned in Chap. 5.

Physiologic and Anatomic Considerations. The majority of investigations aimed at identifying cholinergic transmission mechanisms have utilized the somatic myoneural junction because of its accessibility in relation to other cholinergic synapses. Although the term synapse was originally proposed to describe a nerve-nerve junction, it is commonly used in reference to neuroeffector junctions. A representation of a somatic neuromuscular junction (synapse) and proposed sites of drug actions are shown in Fig. 8.3.

Terminal branches of a motor axon lose their myelin sheath and embed within invaginations of the cell membrane of the skeletal muscle cell; these invaginations are termed synaptic gutters. A synaptic gutter, in turn, has many microinvaginations or infoldings called either junctional folds or subneural folds. The space within the synaptic gutter between the nerve ending and the muscle cell is called the synaptic cleft. "Presynaptic" refers to axonal elements, whereas "postsynaptic" refers to constituents of the muscle cell.

Vesicular structures localized within cholinergic nerve terminals represent storage sites for ACh (see Chap. 5). As an axonal action potential arrives at the nerve terminal, it increases the release of ACh from the storage vesicles into the synaptic cleft. This step (excitation-secretion coupling) is dependent upon mobilization into the neuron of extracellular Ca^{++} and/or Ca^{++} bound to superficial membrane areas of the nerve terminal. Released ACh reacts with the specialized

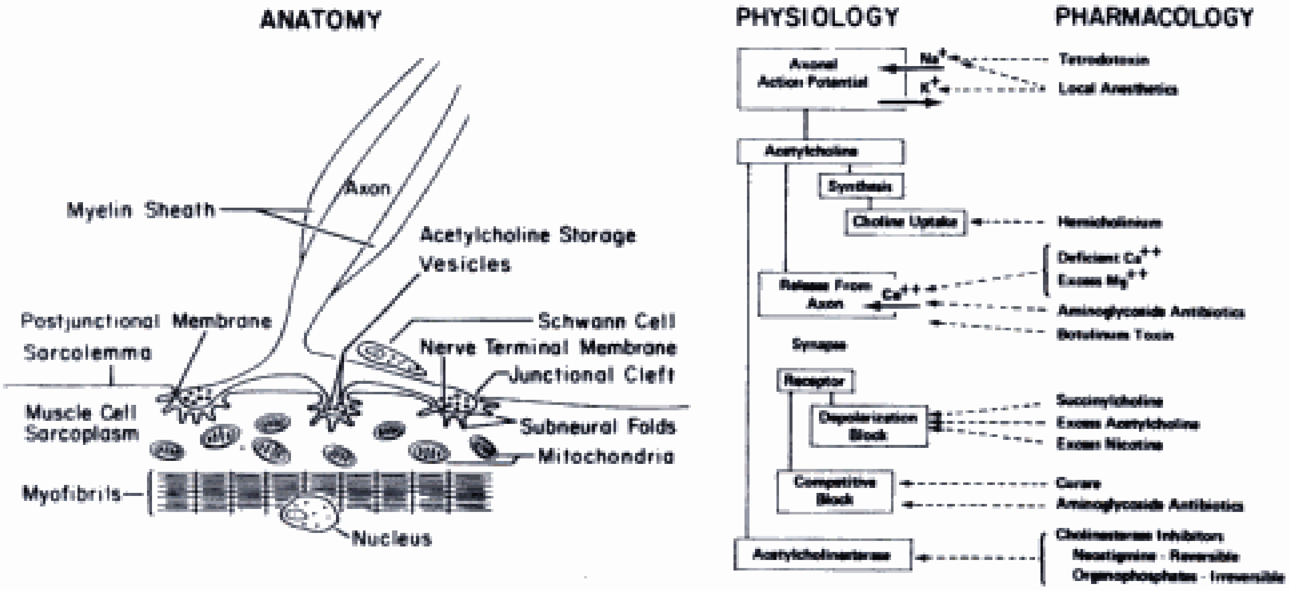

FIG. 8.3—Schematic representation of a somatic neuromuscular junction (synapse), related physiologic pathways, and proposed sites of action of various pharmacologic agents. An axonal action potential (AP) is characterized by an influx of Na^+ and an efflux of K^+. Tetrodotoxin and saxitoxin inactivate Na^+ pathways. Local anesthetics block Na^+ and K^+ pathways. Choline uptake into the neuron is blocked by hemicholinium; synthesis of ACh is prevented. As the AP arrives at the nerve terminal, it instigates inward movement of Ca^{++}; this triggers discharge of ACh into the junctional cleft. A lack of Ca^{++} or an excess of Mg^{++} decreases release of ACh. Aminoglycoside antibiotics also interfere with Ca^{++}-dependent release of ACh. Botulinum toxin inhibits ACh release. Decamethonium and succinylcholine (depolarizing neuromuscular blocking agents) cause persistent depolarization block of the motor end-plate region, as do excess ACh and nicotine. Curare, gallamine, and pancuronium (competitive neuromuscular blocking agents) compete with ACh for postjunctional receptors but do not cause depolarization. Aminoglycoside antibiotics decrease sensitivity of the postjunctional membrane to ACh. Catabolism of ACh by acetylcholinesterase is inhibited by reversible and irreversible anticholinesterase agents; ACh accumulates. (Modified from Taylor 1990b; Couteaux 1972.)

receptor sites of the subsynaptic membrane and causes depolarization of this structure. Cholinergic receptors of somatic myoneural junctions are classified as nicotinic; they are located on the outer membrane of the muscle cell and are almost exclusively confined to the postsynaptic membrane. After denervation, sensitivity to ACh spreads over the entire muscle cell.

Extraneuronal ACh is rapidly metabolized by acetylcholinesterase (AChE) enzyme, which is localized in the end-plate region. Although it may be bound in part to presynaptic elements, it is concentrated at the postsynaptic membrane (Inestrosa and Perelman 1990; Hucho et al 1991).

ACh-induced depolarization of the subsynaptic membrane can be measured as a change in the electric potential of the motor end-plate region, i.e., the end-plate potential. If the end-plate potential is above a threshold level, it instigates a muscle action potential, leading to depolarization of immediately adjacent areas of the postsynaptic membrane. Subsequently, the muscle action potential is propagated along the remainder of the muscle cell membrane. Contraction of skeletal muscle is initiated by the muscle action potential causing a release of Ca^{++} into the cytoplasm from the intracellularly located sarcoplasmic reticulum. The increased free intracellular Ca^{++} binds with troponin, a protein constituent of tropomyosin that acts to inhibit sliding of the actin and myosin filaments during the resting state. Ca^{++}-bound troponin loses this function; cross-linkages are formed between actin and myosin, and sliding of these filaments occurs. The muscle contracts. Miniature end-plate potentials represent subthreshold depolarizations of the motor end-plate region that are due to spontaneous neuronal release of small amounts of ACh; they do not instigate muscle contraction.

Pharmacologic Considerations. The neuromuscular junction is quite susceptible to alteration by selective pharmacologic agents. Various drugs, toxins, electrolytes, and other agents alter in different manners the synthesis, storage, release, receptor interactions, and catabolism of ACh. Several important factors affecting cholinergic transmission are outlined in Fig. 8.3.

Hemicholinium and triethylcholine compete with choline for choline uptake into cholinergic neurons; ACh synthesis is prevented by lack of choline. Existing vesicular stores of ACh are exhausted upon nerve stimulation, and a gradual weakening and eventual paralysis result.

Nerve conduction is affected by only a few substances. The local anesthetics, when in high concentration and immediate contact with the axon, act to stabilize the nerve by inactivating both Na^+ and K^+ channels so that axonal action potential propagation is halted. The pufferfish poison tetrodotoxin and the shellfish poison saxitoxin decrease the permeability of excitable membranes to Na^+ (but not K^+); thus axonal action potentials are not generated, and paralysis results. These toxins do not cause an initial depolarization of nerves; they act noncompetitively, are approximately 100,000 times more potent than cocaine or procaine, and are frequently used in research. Clinical cases of fatal food poisoning have been attributed to ingestion of these substances.

Botulinum toxin is an extremely potent substance (lethal dose for a mouse is 4×10^7 molecules) produced by *Clostridium botulinum.* It is ingested occasionally by humans and lower animals and often is fatal. It decreases the amount of ACh released from cholinergic nerves.

Magnesium ions (Mg^{++}) interfere with release of ACh from the nerve terminal by competing for the transport mechanisms responsible for mobilization of Ca^{++} into the nerve. Mg^{++} uncouples the excitation-secretion coupling process. An insufficient concentration of Ca^{++} produces similar effects. Mg^{++} also acts postsynaptically to decrease the effectiveness of ACh to activate receptors.

Aminoglycoside antibiotics (i.e., neomycin-streptomycin group) inhibit release of ACh from motor nerves by decreasing availability of Ca^{++} at superficial membrane binding sites of the axonal terminal, thereby inhibiting the excitation-secretion coupling process. These antibiotics also reduce sensitivity of the postsynaptic membrane to ACh (Adams 1984).

Cholinesterase inhibitors (see Chap. 7) decrease the hydrolytic activity of AChE and pseudocholinesterase (Taylor 1990a, 1991). ACh rapidly accumulates at receptor sites. Muscle fasciculations, spasms, convulsions, and eventually apnea occur after overdosage with cholinesterase inhibitors.

POSTJUNCTIONAL MECHANISMS OF NEUROMUSCULAR BLOCKADE. The preceding examples illustrate the complexity of neuromuscular transmission and the numerous sites susceptible to many agents and toxins. However, the pharmacologic effects of clinically useful neuromuscular blocking drugs can best be explained by a direct alteration of the effectiveness of ACh to activate postjunctional (postsynaptic) receptors. According to the mechanisms of postjunctional action, neuromuscular blocking agents are classified as either a competitive (nondepolarizing) or a depolarizing agent.

Competitive (Nondepolarizing) Agents. These drugs compete with ACh for available cholinergic receptors at the postsynaptic membrane and, by occupying these receptors, prevent the transmitter function of ACh. A prototype of this group of drugs is *d*-tubocurarine (*Tubocurarine Chloride,* USP, Tubarine). Other similarly acting agents include *Metocurine Iodide,* USP (Metubine) (previously referred to as dimethyl tubocurarine iodide), gallamine (*Gallamine Triethiodide,* USP, Flaxedil), and pancuronium (*Pancuronium Bromide,* Pavulon). Newer competitive agents include fazadinium, a rapidly acting drug that undergoes hepatic biotransformation; alcuronium; atracurium, a synthetic compound that undergoes spontaneous and enzymatic degradation to inactive metabolites; and vecuronium, a derivative of pancuronium (Taylor 1990b; Agoston et al. 1992). Pharmacologic characteristics of several neuromuscular blocking agents are summarized in Table 8.1.

Ultrarefined experimental techniques (e.g., measurement of single-cell electrical activity and microionophoretic application of drugs) have verified the primary site of action of competitive blocking agents as the subsynaptic membrane (Bowen 1972; Hubbard and Quastel 1973). At this region, *d*-tubocurarine is believed to have the same or similar affinity as ACh for cholinergic receptors; i.e., *d*-tubocurarine can interact with these sites as well as ACh. However, *d*-tubocurarine does not exhibit agonistic properties, whereas ACh is extremely active. Although *d*-tubocurarine binds to or in some way interlocks with the cholinoceptors, it has no depolarizing activity and therefore does not cause an end-plate potential. Moreover, the *d*-tubocurarine-receptor interaction renders affected receptors unavailable for interaction with ACh. ACh-induced end-plate potentials are reduced to subthreshold levels or abolished in curarized muscles. In the absence of induced end-plate potentials and subsequent muscle action potentials, the muscle relaxes and is, in fact, paralyzed.

The competitive mechanism of nondepolarizing agents is readily demonstrable. In essence, *d*-tubocurarine blockade of receptors increases the threshold of the end-plate region to ACh. Increasing the concentration of ACh will overcome the blockade produced by *d*-tubocurarine and restore neuromuscular transmission. Correspondingly, reincreasing the concentration of *d*-tubocurarine will again decrease the effectiveness of ACh.

Based on competitive interaction between nondepolarizing agents and ACh, cholinesterase inhibitors were found to be effective in antagonizing effects of these blocking agents. Cholinesterase inhibitors prevent the enzymatic catabolism of ACh. More ACh is available for interaction with cholinoceptors and thereby decreases effectiveness of competitive blocking agents. This relationship has been exploited clinically in successful efforts to terminate effects of nondepolarizing agents. However, cholinesterase inhibitors do not antagonize effects of the other class of neuromuscular blockers, the depolarizing drugs.

Depolarizing Agents. *Succinylcholine Chloride,* USP (Quelcin, Anectine, Sucostrin, Suxamethonium), and *Decamethonium Bromide,* USP (Syncurine, C-10), are members of this group of agents. These drugs exert their skeletal muscle paralyzing effects by interfering with ACh-mediated depolarization of the postsynaptic

Table 8.1—Characteristics of neuromuscular blocking agents

Generic name	Trade name	Chemical class	Duration properties	Onset (min)	Duration (min)	Biotransformation
Depolarizing Agents						
Succinylcholine	Anectine	Choline ester	Ultrashort	<2	6-8	Hydrolysis by plasma cholinesterases
Nondepolarizing (Competitive) Agents						
d-Tubocurarine		Natural alkaloid (cyclic benzylisoquinoline)	Long	4-6	80-120	Renal elimination; liver clearance
Atracurium	Tracrium	Benzylisoquinoline	Intermediate	2-4	30-40	Spontaneous degradation; hydrolysis by plasma cholinesterases
Doxacurium	Nuromax	Benzylisoquinoline	Long	4-6	90-120	Renal elimination; liver metabolism and clearance
Mivacurium	Mivacron	Benzylisoquinoline	Short	2-4	12-18	Hydrolysis by plasma cholinesterases
Pancuronium	Pavulon	Ammonio steroid	Long	4-6	120-180	Renal elimination; liver metabolism and clearance
Pipecuronium	Arduan	Ammonio steroid	Long	2-4	80-100	Renal elimination; liver metabolism and clearance
Rocuronium	Zemuron	Ammonio steroid	Intermediate	1-2	30-40	Liver metabolism; renal elimination
Vecuronium	Norcuron	Ammonio steroid	Intermediate	2-4	30-40	Liver metabolism and clearance; renal elimination

membrane. In contrast to the well-defined mechanism of the competitive agents, certain aspects of the mechanism(s) of depolarizing neuromuscular blockers are continually debated.

Succinylcholine and related drugs interact with postsynaptic cholinergic receptors but cause distinctly different effects than curare-like drugs. Initially, an end-plate potential and a corresponding muscle action potential are elicited upon exposure to succinylcholine. These depolarization changes in membrane potential are similar to those produced by the endogenous mediator ACh. However, ACh is immediately hydrolyzed by cholinesterase; the postsynaptic membrane repolarizes and is prepared for subsequent activation by additional quanta of ACh. Succinylcholine elicits a prolonged depolarization of the end-plate region that does not allow the subsynaptic membrane to completely repolarize and renders the motor end-plate nonresponsive to the normal action of ACh.

Because of the initial depolarizing action, transient contraction of muscle cells occurs after administration of succinylcholine and related agents. This is characterized in vivo as momentary asynchronous muscle twitches and fasciculations. Because of the persistent depolarization of the postsynaptic membrane, however, subsequent impulse transmissions are blocked and a flaccid type of paralysis ensues. The molecular mechanism(s) of depolarizing neuromuscular blocking agents is not completely understood but may be biphasic.

PHASE I BLOCK. Depolarization of the motor end-plate region by ACh is characterized by increased permeability of the subsynaptic membrane to Na^+ and K^+. As ACh is catabolized by AChE the selective permeability characteristics of the postsynaptic membrane are rapidly reestablished. Repolarization occurs. Succinylcholine, however, causes a persistent increase in permeability of the postsynaptic membrane to Na^+ and K^+. ACh cannot act as a transmitter, and impulse transmission fails. It should be remembered that ACh, when in excess, also causes persistent depolarization block of cholinergic synaptic junctions.

PHASE II BLOCK. Phase II block occurs in some instances after prolonged exposure to a depolarizing agent and is characterized by a change from the depolarizing block to one that in some ways resembles that caused by curare. The actual mechanisms involved are poorly understood and opinion is contradictory as to this transition. Zaimis (1959) believes, e.g., that confusion has occurred because in some species some blocking agents have a "dual mechanism"; i.e., they cause some effects that resemble depolarization block and cause other effects that resemble competitive blockade.

After exposure of isolated nerve-muscle preparations to succinylcholine, the initial peak level of depolarization subsides. Subsequently, the end-plate becomes transiently sensitive to depolarizing agents. Gradually, a competitive-like blockade results and

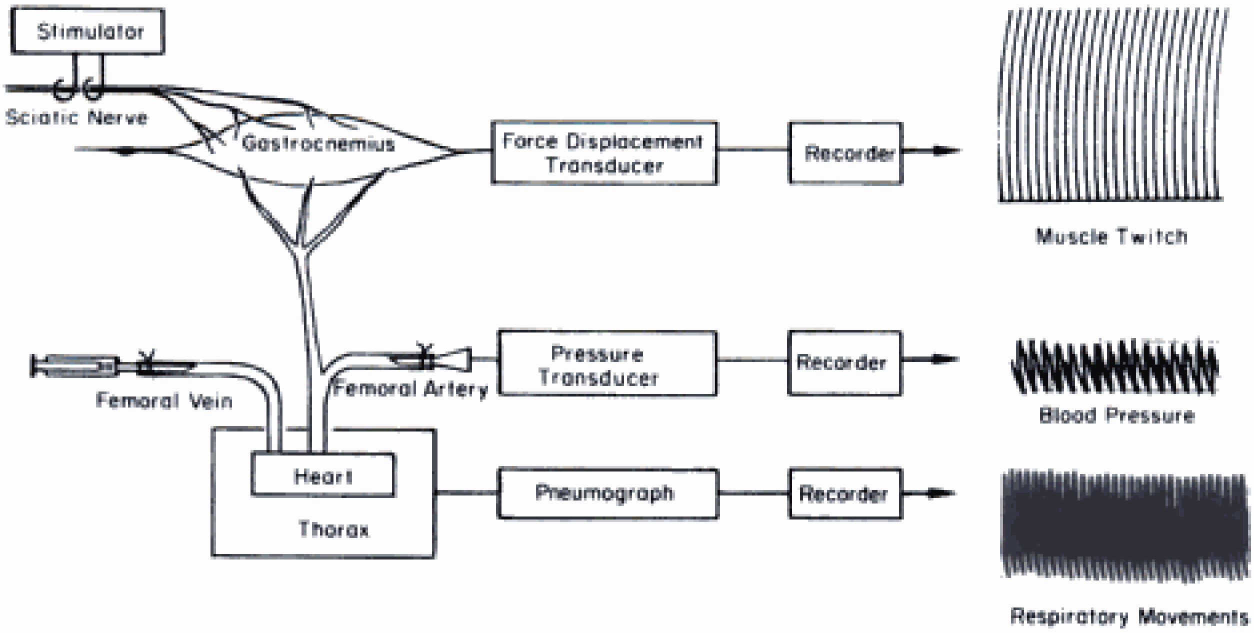

FIG. 8.4—Schematic representation of a sciatic nerve-gastrocnemius muscle preparation in an anesthetized cat. Stimulation of the isolated and decentralized sciatic nerve evokes contraction (muscle twitch) of the gastrocnemius muscle. Femoral arterial blood pressure and respiratory movements can be measured concurrently. Neuromuscular blocking drugs can be administered intravenously and changes in muscle twitch height observed.

seems to be at least partially susceptible to reversal by cholinesterase inhibitors. Tachyphylaxis to depolarizing agents quickly develops and the receptors now appear to be insensitive to ACh. However, the importance of Phase II has not been clearly defined for each depolarizing neuromuscular blocking agent.

As a group the depolarizing neuromuscular blocking agents cause depolarization of receptor areas of muscle fibers sometime during their course of action. Increasing availability of ACh by administration of a cholinesterase inhibitor has no effect or in some cases may actually intensify the neuromuscular block of a depolarizing agent. Just the opposite, cholinesterase inhibitors can be quite effective in antagonizing the competitive block produced by nondepolarizing curaremimetic agents.

PHARMACOLOGIC EFFECTS OF NEUROMUSCULAR BLOCKING AGENTS

Skeletal Muscle

COMPETITIVE NEUROMUSCULAR BLOCKING AGENTS. Nondepolarizing curare-like drugs paralyze skeletal muscle by neuromuscular blockade. These agents interact with nicotinic cholinergic receptors of skeletal muscle cells and render them inaccessible to the transmitter function of ACh. Flaccid paralysis occurs. Neither axonal conductance nor response to direct stimulation of muscle is blocked by curare agents.

A schematic representation of an in vivo nerve-muscle preparation is shown in Fig. 8.4. This sciatic nerve-gastrocnemius muscle preparation of anesthetized cats is often used to examine actions and interactions of neuromuscular blocking agents. In this preparation, stimulation of the sciatic nerve causes contraction (kg of isometric tension) of the gastrocnemius muscle.

Fig. 8.5 demonstrates the neuromuscular blocking effect of *d*-tubocurarine on indirectly stimulated muscle twitch of the sciatic nerve-gastrocnemius muscle preparation of a cat, as described in Fig. 8.4. In this example, muscle twitch quickly decreases after intravenous (IV) injection of *d*-tubocurarine, reaches peak depression within a few minutes, and then gradually returns to normal in approximately 15 minutes. Tubocurarine does not evoke an initial increase in muscle twitch; this lack of facilitation is a consistent finding with nondepolarizing agents. Gallamine, metocurine, and pancuronium produce similar characteristics of neuromuscular paralysis. Metocurine is 3-10 times more active than *d*-tubocurarine, pancuronium is 5-7 times more potent than *d*-tubocurarine, and gallamine is somewhat less active.

Antagonism of the neuromuscular blocking effects of *d*-tubocurarine by administration of a cholinesterase inhibitor, neostigmine, is shown in Fig. 8.5. By comparing the two tracings in this figure, it is readily apparent that neostigmine markedly hastens recovery from the muscle twitch depression caused by *d*-tubocurarine. This antagonistic interaction is primarily attributed to the anticholinesterase activity of neostigmine. Inhibition of cholinesterase delays the catabolic breakdown of ACh and allows its accumulation at receptor

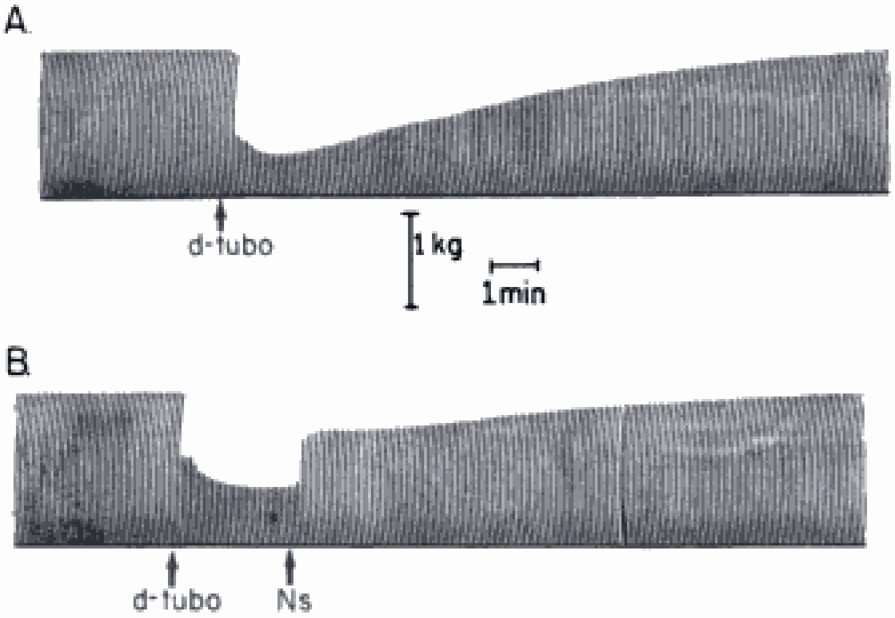

FIG. 8.5—Neuromuscular blocking effect of *d*-tubocurarine (*d*-tubo) and reversal of the *d*-tubo by neostigmine in a sciatic nerve-gastrocnemius muscle preparation of a cat. The cat was anesthetized with pentobarbital; muscle twitch was monitored as described in Fig. 8.4. (A) Typical depression of muscle twitch by *d*-tubo (0.2 mg/kg) administered intravenously at designated arrow. (B) Antagonism of *d*-tubo (0.2 mg/kg) induced depression of muscle twitch by neostigmine (Ns; 0.1 mg/kg). Agents were administered intravenously at arrow. Notice rapid antagonism of the neuromuscular blocking effect of *d*-tubo by Ns. Compare this with the lack of antagonism by Ns of the muscle twitch depressant effect of succinylcholine in Fig. 8.6.

sites. Newly available ACh, now in increased concentration at the post-synaptic membrane, effectively competes with *d*-tubocurarine for the cholinoceptors. ACh-mediated depolarization of the end-plate, muscle action potentials, and muscle contraction are restored; muscle twitch quickly returns to normal.

DEPOLARIZING NEUROMUSCULAR BLOCKING AGENTS. Succinylcholine and decamethonium elicit transient muscle fasciculations prior to causing neuromuscular paralysis. This is due to initial depolarization of the motor end-plate and is characterized in the intact animal by asynchronous muscular contractions of the head, body trunk, and limbs. Fasciculation does not always occur in anesthetized animals.

The in vivo neuromuscular blocking effect of a small dose of succinylcholine in a cat nerve-muscle preparation is shown in Fig. 8.6. Initially, there is a slight and transient facilitory effect of succinylcholine on neuromuscular transmission; muscle twitch height momentarily increases by a small increment as a result of the initial depolarizing effect of the drug. Subsequently, however, muscle twitch rapidly decreases and within 1-2 minutes maximum depressant effect is obtained. Shortly thereafter, the neuromuscular effects of succinylcholine subside and muscle twitch returns to normal within an additional 5-8 minutes. The magnitude and duration of neuromuscular paralysis is dependent upon the dosage of succinylcholine. The relatively short duration of succinylcholine activity is from rapid biotransformation of this drug by plasma pseudocholinesterase. Decamethonium causes similar characteristics of neuromuscular blockade, but the duration of action of this drug is considerably longer than that seen with succinylcholine.

The effects of a cholinesterase inhibitor, neostigmine, on the neuromuscular paralysis produced by succinylcholine are demonstrated in Fig. 8.6. By comparing the two tracings in this figure, it is apparent that neostigmine potentiated the muscle twitch depression evoked by succinylcholine and prolonged recovery from the effects of this agent. This synergistic interaction is primarily attributed to the anticholinesterase activity of neostigmine, resulting in decreased biotransformation of both succinylcholine and endogenous ACh. Thus succinylcholine and ACh are available at receptor sites for longer periods and the duration of depolarizing neuromuscular paralysis is prolonged.

The potency of neuromuscular effects of succinylcholine varies in different species (Hansson 1958), as shown schematically in Fig. 8.7. Bovine and canine species are quite sensitive to succinylcholine, whereas horses and pigs are considerably less responsive. This difference is probably dependent upon species differences in the activity of pseudocholinesterase, the enzyme that biotransforms succinylcholine (Radeleff and Woodard 1956; Palmer et al. 1965). Cattle and sheep, e.g., have considerably less detectable pseudocholinesterase activity than horses and pigs. Administration of purified pseudocholinesterase preparation to dogs increases resistance to succinylcholine (Hall et al. 1953).

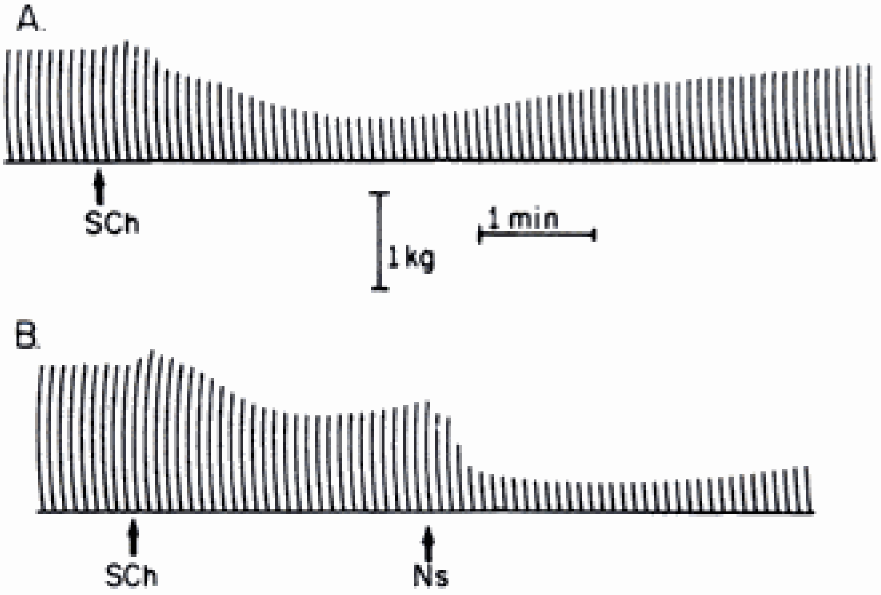

FIG. 8.6—Neuromuscular blocking effect of succinylcholine (SCh) and augmentation of its effect by neostigmine (Ns) in a sciatic nerve-gastrocnemius muscle preparation of a cat. The cat was anesthetized with pentobarbital; muscle twitch was monitored as described in Fig. 8.4. (A) Typical depression of muscle twitch by SCh (0.04 mg/kg) administered intravenously at designated arrow. (B) Augmentation of the muscle twitch depressant effect of SCh (0.04 mg/kg) by Ns (0.1 mg/kg). Agents were administered intravenously at designated arrows. Notice augmentation of the degree and duration of effect of SCh by Ns. Compare this with the antagonism by Ns of the neuromuscular blocking effect of *d*-tubo in Fig. 8.5.

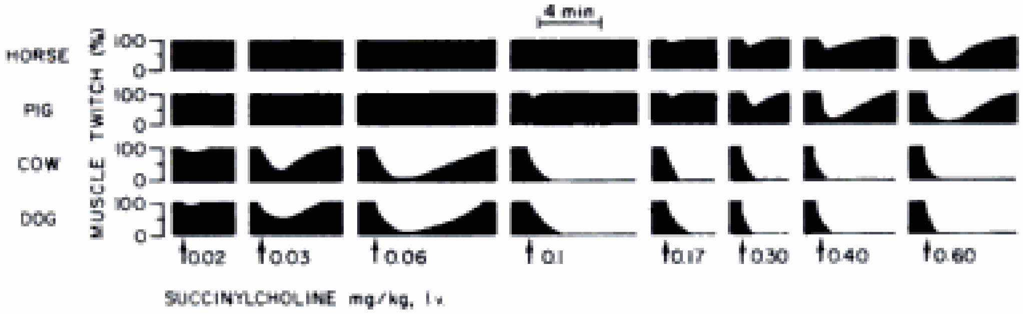

FIG. 8.7—Schematic representations of the neuromuscular blocking effect of succinylcholine iodide in nerve-muscle preparations of different species during barbiturate anesthesia. Notice interspecies differences in degree and duration of paralysis caused by succinylcholine. (Modified from Hansson 1956, after Lumb and Jones 1973.)

Autonomic Effects. Synaptic transmission at autonomic ganglia involves activation by ACh of nicotinic receptors of the postganglionic nerve body (see Chap. 7). It is not surprising, therefore, that neuromuscular blocking agents (which act at somatic nicotinic sites) may also alter ganglionic transmission.

Tubocurarine is an excellent example of a drug selected for site of action at nicotinic receptors of the somatic myoneural junction that as a side effect also acts at ganglionic nicotinic receptors. Tubocurarine interacts with ganglionic receptors, renders them inaccessible to ACh, and thereby increases the threshold of the postganglionic nerve to ACh. However, as a general rule, autonomic ganglia are less sensitive to curare than are the myoneural junctions. Ganglionic impulse transmission involves, at least partially, a muscarinic pathway (see Chap. 7); *d*-tubocurarine has little blocking effect on muscarinic receptors. Thus in most cases it would be anticipated that ganglionic transmission is functional during treatment with curare-like drugs. Nevertheless, hypotension believed to be partly dependent upon ganglionic blockade can occur after administration of *d*-tubocurarine.

Other neuromuscular blocking drugs, both competitive and depolarizing types, have been shown experimentally to alter ganglionic transmission, but in clinically insignificant amounts. Succinylcholine induces transient ganglionic stimulation prior to blockade evoked by larger doses. The former effect may partially explain hypertension that has occurred subsequent to succinylcholine administration.

Parasympathetic effects of neuromuscular blocking agents are usually minimal. Pancuronium has anticholinesterase activity. Succinylcholine and decamethonium are approximately 1000 times and 100 times less potent respectively than ACh in eliciting contraction of guinea pig ileum. In dogs, large doses of succinylcholine induce salivation; this is antagonized by pretreatment with atropine (Hansson 1956).

Histamine Release. Tubocurarine causes release of histamine. The magnitude of this response varies, depending on species, dosage, and rate and route of administration. Intra-arterial infusion of *d*-tubocurarine evokes histamine release in the perfused hind-limb preparation of dogs, and histamine-like wheals can be produced by subdermal and intra-arterial administration of *d*-tubocurarine. In vivo, increased respiratory tract secretions and bronchospasm seen after administration of *d*-tubocurarine have been attributed to histamine release, as has the hypotensive effect of *d*-tubocurarine. Pretreatment with antihistamine drugs antagonizes these side effects; they are not inhibited by atropine or neostigmine.

Metocurine, succinylcholine, decamethonium, and gallamine are very weak histamine-releasing agents.

Central Nervous System. Although synaptic transmission in the brain is altered by direct application of neuromuscular blocking drugs into the brain, CNS effects are nondetectable when these drugs are administered by other routes. Neuromuscular blocking agents do not gain entry into the CNS to any appreciable extent because of the presence of the highly charged quaternary ammonium moieties. Therefore, neither CNS depression nor tranquilization is produced by neuromuscular blocking agents. Nonambulation results only from peripheral myoneural paralysis. This was decisively confirmed when Smith (Smith et al. 1947) allowed himself to be paralyzed with *d*-tubocurarine. At no time during the experiment did he experience hypnosis, tranquilization, amnesia, anesthesia, or analgesia. He simply could not voluntarily breathe or move, an experience described as quite frightful.

Cardiovascular Effects. As outlined above, *d*-tubocurarine often induces hypotension, particularly if rapidly administered to dogs. Slight increases in heart rate and cardiac output have been observed after administration of gallamine, apparently from a vagolytic effect on the heart (Longnecker et al. 1973). Others have reported no significant cardiovascular changes after IV administration of gallamine to anesthetized dogs (Evans et al. 1977). In cats, mild atropine-like effects on the heart were observed after injection of gallamine, pancuronium, and alcuronium chloride (Alloferin) (Hughes and Chapple 1976).

Studies with pancuronium in humans and dogs indicated that this agent evokes slight increases in heart rate, blood pressure, and cardiac output during thiobarbiturate anesthesia (Coleman et al. 1972; Reitan and Warpinski 1975). Cardiovascular effects of this agent were absent if patients were pretreated with atropine. Others have reported no significant cardiovascular changes with pancuronium (Brown et al. 1973). Similarly, studies have indicated that neither pancuronium nor gallamine significantly altered heart rate or blood pressure in anesthetized horses (Klein et al. 1983). Atracurium (up to 0.6 mg/kg) and vecuronium (up to 0.2 mg/kg) were reported to have negligible effects on arterial blood pressure in dogs (Jones 1985).

Succinylcholine usually evokes minimal cardiovascular changes in horses or dogs if administered during general anesthesia; blood pressure remains fairly constant if artificial breathing is provided (Evans et al. 1977; Benson et al. 1979).

Subparalytic doses of succinylcholine increase the arrhythmogenicity of epinephrine during light halothane anesthesia in dogs (Tucker and Munson 1975). In dogs not treated with succinylcholine, an average dose of 4.15 μg/kg epinephrine was required to evoke premature ventricular contractions, whereas an average dose of 1.6 μg/kg epinephrine was the arrhythmogenic dose in dogs pretreated with 0.25 mg/kg succinylcholine. However, *d*-tubocurarine provides a slight protection against epinephrine-induced arrhythmias. Mechanisms involved in these drug interactions have not been clarified. If deemed essential, catecholamines should be used cautiously in patients treated with depolarizing neuromuscular blocking agents.

Also, succinylcholine has been reported to increase susceptibility to the myocardial irritant effects of digitalis preparations, and it has been suggested that succinylcholine may be contraindicated in digitalized patients (Dowdy et al. 1965).

Pronounced cardiovascular side effects have been reported in horses after administration of succinylcholine (Larson et al. 1959; Hofmeyer 1960; Lees and Tavernor 1969). In general, these effects seem to be more pronounced in unanesthetized and nontranquilized animals than during general anesthesia. Severe hypertension, initial bradycardia followed by tachycardia, atrioventricular conduction disturbances, and extrasystoles have been reported, and myocardial damage has been suspected. Early institution of artificial respiration has been reported to block the blood pressure effect. The hypertensive response seems to be at least partially mediated by the succinylcholine-induced dyspnea and the accompanying blood PO_2-PCO_2 disturbances, causing a reflexogenic increase in blood pressure. Direct activation of autonomic ganglia by succinylcholine may also be involved.

It should be remembered that neuromuscular blocking agents do not depress the brain unless or until apnea-induced hypoxia actually causes syncope. Prior to hypoxic states, skeletal muscle paralysis affords no depression whatsoever of conscious centers of the brain of nonanesthetized animals. It seems likely, then, that the novel sensations experienced by conscious animals as they are being paralyzed evoke profound fright. This can cause activation of autonomic centers within the brain. Autonomic discharge may be altered markedly resulting in cardiovascular side effects. Autonomic blocking agents (ganglionic block with hexamethonium, β-adrenergic block with propranolol) substantially decrease the cardiovascular side effects of succinylcholine.

Ocular Effects. Clinically important ocular effects depend upon the pronounced contracture of ocular muscles that occurs after treatment with depolarizing neuromuscular blockers. These agents are contraindicated in glaucoma, since intraocular pressure may be increased.

Serum Potassium. Depolarizing neuromuscular blocking agents cause a release of K^+ from skeletal muscle. Elevation of serum K^+ may result, particularly if repeated injections are given.

Pharmacokinetics. Neuromuscular blocking agents with quaternary nitrogen groups are ionized at all levels of physiologic pH. Therefore, they are highly charged, lipophobic compounds and cross lipoprotein membrane barriers poorly. Little if any absorption occurs after oral administration of these drugs. South American Indians were well aware of this, since they ingested flesh of curare-poisoned animals without concern. Inefficient absorption after oral administration has little importance to modern medicine, however, because these agents should be given by the IV route so that muscle relaxation can be quickly evaluated. Whereas South American Indians were concerned only with one end point, death, and were worried only about underdosage, practitioners are concerned with facilitating muscle relaxation and are extremely concerned with overdosage. Administration of neuromuscular blocking agents should be closely monitored and correlated at all times, with effects observed in the patient.

Intramuscular (IM) injection of neuromuscular blocking agents is occasionally used to immobilize nondomestic animals. Absorption occurs rapidly after IM injection, and effective blood concentrations are obtained shortly thereafter.

Tubocurarine is distributed primarily in the extracellular space throughout body tissues, but it concentrates at myoneural junctional regions (Waser 1967). It penetrates cells poorly because of the charged state of the molecule. The liver and kidney participate in the biologic fate of *d*-tubocurarine; however, duration of action of this agent normally does not depend upon biotransformation. Rather, redistribution of *d*-tubocurarine away from the neuromuscular junction and into nonspecific body compartments is believed to account for the short duration of action of a single dose of this drug. Repeated treatment or excessive amounts of *d*-tubocurarine tends to saturate nonspecific sites. Under these circumstances, renal excretion becomes important as a mechanism for termination of activity of *d*-tubocurarine. If injection must be repeated, less drug is needed to evoke muscle relaxation. Cumulative neuromuscular blockade occurs when injections are repeated, since *d*-tubocurarine is excreted rather slowly by the kidneys.

Gallamine and metocurine are probably handled similarly to *d*-tubocurarine. Gallamine is excreted virtually unchanged in the urine, as are decamethonium and pancuronium. These agents are thought to bind only minimally to tissues. Renal failure markedly prolongs their duration of action.

Atracurium is one of a series of new competitive agents that was developed to overcome pharmacokinetic disadvantages of the older drugs. Atracurium is rapidly inactivated by plasma esterases and also, importantly, by a spontaneous chemical degradation instigated at physiologic pH and body temperature (Table 8.1). Atracurium is therefore noncumulative, and the duration of action of the same dose does not increase with repetitive injections (Agoston et al. 1980). In dogs, Jones (1985) recommended that atracurium be administered initially at 0.5 mg/kg, followed by increments of 0.2 mg/kg. The duration of neuromuscular blocking action of vecuronium, another new agent, is similar to that of atracurium and is about one-third to one-half that of pancuronium. Vecuronium undergoes hepatic biotransformation and is excreted predominantly in the bile; it is somewhat cumulative, and this characteristic can be expected to be more pronounced in the presence of hepatic disease (Jones 1985). Because of its short duration of action and affiliated ease of control, atracurium has become a frequently used neuromuscular blocking agent in veterinary anesthesiology.

Succinylcholine is rapidly disposed of by the body, since it is a suitable substrate for plasma pseudocholinesterase. This enzyme quickly hydrolyzes succinylcholine to the considerably less active metabolite succinylmonocholine. This metabolite is more slowly broken down by pseudocholinesterase to succinic acid and choline, natural body constituents. The interspecies potency of succinylcholine varies considerably. This has been attributed to species differences in activity of pseudocholinesterase.

INTERACTIONS. Various drugs influence the pharmacologic effects of muscle relaxants. Neuromuscular blocking agents themselves alter activity of other neuromuscular agents. As would be expected, competitive agents summate with each other. Similarly, depolarizing agents also interact synergistically with one another. However, tubocurarine decreases the muscle twitch depressant effects of succinylcholine and decamethonium. This is related to persistent occupation of a certain portion of receptors by tubocurarine, although muscle twitch may have recovered (see margin of safety of neuromuscular transmission below). Depolarization of the end-plate by succinylcholine or decamethonium is partially impeded by the stabilizing effects of tubocurarine. Succinylcholine antagonizes the effects of curare as a result of the partial agonistic characteristics of the former agent. These complex antagonistic interactions, however, have no clinical application, since they depend upon complicated treatment and time and dosage schedules. During clinical situations, neuromuscular blocking agents should not be used in attempts to reverse the effects of other types of neuromuscular blocking agents, since potentiation may occur despite experimental results to the contrary.

The interaction of cholinesterase inhibitors with neuromuscular blocking agents has been discussed above. Cholinesterase inhibitors decrease responsiveness to the competitive agents, while they tend to increase intensity and duration of action of depolarizing agents (Sunew and Hicks 1978). Organophosphate pesticides and anthelmintics, carbamates, and any other cholinesterase inhibitor may cause interactions. The phenothiazine family of tranquilizers has some anticholinesterase activity. Use of succinylcholine in a patient exposed to an organophosphate may be particularly hazardous if a phenothiazine tranquilizer has also been administered.

Many general anesthetics, in addition to depressing the CNS, depress impulse transmission at somatic myoneural junctions. Halothane acts synergistically with curare-like drugs but to a lesser extent than ether. Methoxyflurane and pentobarbital also have depressant effects on myoneural transmission events.

Aminoglycoside antibiotics (neomycin, streptomycin, dihydrostreptomycin, kanamycin, gentamicin) decrease the release of ACh from the nerve and also the sensitivity of the end-plate to ACh (Pittinger and Adamson 1972; Adams et al. 1976a). They do not cause depolarization. Their effects in many ways resemble those of low Ca^{++} or excess Mg^{++}. The presynaptic effect of antibiotics is believed to be due to interruption of Ca^{++}-dependent events at the axonal membrane (Adams 1984). Cholinesterase inhibitors such as neostigmine antagonize the post-synaptic depressant effect of these antibiotics. Ca^{++} antagonizes the presynaptic action and is usually more effective than neostigmine in reversing the neuromuscular paralyzing effects of aminoglycoside antibiotics. These antibiotics interact synergistically at the myoneural junction with neuromuscular blocking agents, anesthetics, and other antibiotics. The clinical significance of neuromuscular interactions of antibiotics and other drugs has been well established in humans and has been suggested in lower animals (Adams and Bingham 1971). These subjects have been reviewed (Pittinger et al. 1970; Adams et al. 1976b; Keller et al. 1992).

Different disease states influence pharmacologic effects of neuromuscular blocking agents. Hepatic synthesis of pseudocholinesterase is decreased in the presence of liver disease. The duration of succinylcholine activity will be prolonged if the liver is seriously affected. Administration of purified pseudocholinesterase preparation hastens recovery from effects of succinylcholine (Scholler et al. 1977).

Renal problems delay excretion of *d*-tubocurarine, gallamine, pancuronium, and decamethonium. Anand et al. (1972) successfully reversed persistent gallamine-induced neuromuscular paralysis in a renally incompetent human patient by use of artificial diuresis.

CLINICAL USE. Muscle paralysis proceeds at different rates in different body regions after administration of a neuromuscular blocking agent. Usually, head and neck muscles are affected first, often within 0.25-1 minute after injection. This characteristic is employed in a biologic assay (i.e., head-drop test in rabbits) for determining potency of an unknown concentration of curare. The tail is usually affected with the head and neck. Subsequently, muscles of the limbs are paralyzed, then the deglutition and laryngeal muscles. Abdominal muscles, intercostal muscles, and the diaphragm are then paralyzed in this order. Recovery usually proceeds in the reverse of this sequence (Hall 1971).

Attempts have been made in clinical practice to use the sequential development of muscle paralysis by administering doses of neuromuscular blocking agents adequate to paralyze ambulatory muscle but insufficient to affect the diaphragm. This has not always proved effective, because respiratory insufficiency may still occur, although the diaphragm is seemingly spared. Therefore, it is imperative that apparatus for administering artificial respiration be available when neuromuscular blocking agents are used clinically. To circumvent the need for immediate establishment of an adequate airway and other emergency procedures, it would seem wise to routinely perform tracheal intubation and institute artificial respiration whenever a neuromuscular blocking agent is used.

Muscle relaxants have been used in clinical practice for several purposes: to facilitate tracheal intubation; to paralyze respiratory muscle so that artificial respiration can be easily controlled; to increase muscle relaxation to facilitate surgical access to difficult anatomic regions; to evoke muscle relaxation to facilitate orthopedic manipulations and, particularly, fracture reduction; and as part of balanced anesthesia procedures to reduce the amount of general anesthetic required.

Tracheal intubation may be performed in a nonanesthetized animal immediately after a paralyzing dose of neuromuscular blocking agent has taken effect. Prior administration of a sedative or tranquilizer is advisable for humane reasons and to circumvent potential side effects that may be precipitated by fear reaction to paralysis.

A wide range of dosages of neuromuscular blocking agents has been reported for use of these drugs during anesthesia (Hansson 1956; Tavernor 1971; Lumb and Jones 1973). Often this variance reflects differences in investigative procedures of the original studies, e.g., the use of different anesthetics and sedatives, different salts of the neuromuscular blocking agent, different nerve-muscle preparations, and in some cases the use of nonanesthetized subjects. Neuromuscular blocking agents should be given to effect rather than by bolus administration of a set precalculated dose. It is advisable for these drugs to be administered by titration during anesthesia and to be continuously correlated with muscle relaxation much in the way that barbiturates are administered for induction of general anesthesia.

In dogs, 0.4-0.5 mg/kg *d*-tubocurarine administered intravenously will cause generalized skeletal muscle relaxation, but hypotension frequently occurs as a side effect in this species. In pigs, 0.2-0.3 mg/kg *d*-tubocurarine will usually afford acceptable muscular relaxation; blood pressure effects are less in this species than in the dog. Tubocurarine is somewhat more potent in ruminants; doses of 0.05-0.06 mg/kg have been suggested for use in young lambs and goats.

Approximately 1 mg/kg gallamine causes complete muscle paralysis in both dogs and cats within 1-2 minutes after IV injection and lasts 15-20 minutes. A hypotensive response may be induced in cats with gallamine but is infrequently observed in dogs. In young ruminants (lambs and calves), 0.4 mg/kg gallamine is effective, whereas the dose in horses is 0.5-1 mg/kg.

Solutions of succinylcholine should always be refrigerated and kept on ice in the field, since this agent undergoes spontaneous hydrolysis. Hansson (1956) reported that the IV ED_{50} (dose that reduced muscle twitch by 50%) of succinylcholine in the sciatic nerve-gastrocnemius muscle preparation of anesthetized dogs was 0.045-0.060 mg/kg. This dose did not effectively paralyze the respiratory muscles, however, and 0.085 mg/kg was required to induce transient apnea, whereas 0.11 mg/kg and 0.22 mg/kg were needed to cause apnea for 18-21 minutes and 23-27 minutes respectively. In unanesthetized dogs, IM administration of 0.12 mg/kg succinylcholine caused ataxia in 5 minutes and forced abdominal respiration in 7 minutes; recovery was apparently complete in 30 minutes. In clinical situations, 0.3 mg/kg succinylcholine administered intravenously will usually afford good muscle relaxation in dogs, whereas in the cat, 1 mg/kg may be required. In dogs, Hansson (1956) reported that 0.15 mg/kg succinylcholine was effective in paralyzing the diaphragm during thoracotomy procedures. However, Eyster and Evans (1974) suggested the use of 0.5 mg/kg succinylcholine for muscle relaxation in dogs during thoracotomy for open-heart surgery. This dose was also reported to control muscle twitches evoked by inadvertent stimulation of nerves during use of electrocautery. Duration of paralysis varies and should be closely monitored.

In rhesus monkeys, 1-2 mg/kg succinylcholine administered intravenously has been used for restraint for tuberculosis testing and endotracheal intubation (Lindquist and Lau 1973). In pigs, approximately 2 mg/kg succinylcholine is effective. Much smaller amounts (0.01-0.02 mg/kg) are required in cattle and sheep. Hansson (1956) reported that 0.13-0.18 mg/kg succinylcholine is required to immobilize nonanesthetized horses. However, the generally accepted dose of succinylcholine in horses, when used alone, is 0.088 mg/kg (Lumb and Jones 1973).

Succinylcholine has been used without anesthesia in horses for casting and restraint during brief surgical procedures such as castration. This practice should not be condoned, because no anesthesia is afforded for painful procedures, severe fright is seemingly evoked, and pronounced cardiovascular disturbances and even myocardial damage may result. Succinylcholine should not be used as a sole restraining agent during surgical procedures but only in conjunction with a general or local anesthetic.

Moreover, care should always be taken during the use of neuromuscular blocking agents to ensure that the patient does not simply remain paralyzed after recovery from the anesthetic. This has occurred in human patients and has led to successful lawsuits by patients and receipt of monetary compensation. Although lower animals cannot complain, it behooves us as veterinarians to ensure that our patients are not inadvertently subjected to such excruciatingly painful incidents.

Margin of Safety of Neuromuscular Transmission. The concept of a margin of safety of neuromuscular transmission bears discussion in relation to clinical use of these drugs. It has been estimated that a relatively large percentage of the cholinergic receptors must be occupied by a curare agent before muscle twitch fails. In the cat diaphragm, e.g., muscle twitch is not affected until about 80% of the receptors are blocked by *d*-tubocurarine, and twitch is not completely abolished until about 90% of the receptors are occupied (Waud and Waud 1972). A somewhat greater margin of safety was found in dogs. Accordingly, for recovery of the diaphragm from the effects of a previous injection of *d*-tubocurarine, only a small percentage (5% in dogs, 18% in cats) of the receptors need to be free. Therefore, and most important, although to all outward signs recovery seems complete, over 80% of the receptors can still be blocked.

Recognition of this aspect becomes clinically important in the postoperative recovery room and should be considered in patients that have been exposed to neuromuscular blocking drugs and/or other myoneural depressants such as anesthetics. As a patient regains some control of voluntary muscles, spontaneous respiration returns and may seem completely normal. However, it must be remembered that at this time an extremely small margin of safety of neuromuscular transmission exists. That is, only a small percentage of the postsynaptic receptors are available for interaction with ACh; this small fraction of receptors is now responsible for maintaining muscle contraction. Therefore, if the patient is then exposed to another drug that as a side effect depresses neuromuscular function (even though it may be minimal or even nondetectable normally), disastrous complications may result. Anesthetic mortality has occurred in humans that can be attributed to such interactions. For example, Pridgen (1956) reported the anesthetic deaths of two children who were given neomycin intraperitoneally immediately after completion of successful laparotomies under ether anesthesia. Initially, respiration was adequate, but within a short time after administration of the antibiotic, persistent apnea occurred. Death followed several hours later. It seems likely that the margin of safety of neuromuscular transmission was reduced in these infants by ether, resulting in marked augmentation of the neuromuscular blocking properties of neomycin. Pittinger et al. (1970) estimated a 9% death rate in human patients experiencing antibiotic-induced respiratory problems in conjunction with anesthetics and neuromuscular blocking agents. Apnea and eventual death in a traumatized dog were attributed to antibiotic (dihydrostreptomycin)-induced neuromuscular paralysis (Adams and Bingham 1971).

These examples illustrate potential problems that may be inadvertently introduced in a patient that seemingly is recovering quite well from anesthesia and surgery. The margin of safety of neuromuscular transmission should be considered any time that anesthetics, neuromuscular blocking agents, or any other drug that depresses myoneural function are used in multiple drug regimens.

Clinical Reversal of Neuromuscular Paralysis. Treatment of persistent neuromuscular paralysis and/or treatment of inadvertent overdosage of neuromuscular blocking agents should be approached conservatively (Bevan et al. 1992). The initial step should be immediate artificial respiration and withdrawal of administration of the involved agent. Often, artificial respiration will allow adequate time for the drug to be disposed of by the patient's system. Exposure to other drugs that may synergistically interact with neuromuscular blocking agents should be avoided. If a competitive neuromuscular blocking agent was used, paralysis can usually be effectively antagonized by administration of a cholinesterase inhibitor such as neostigmine or edrophonium (Hildebrand and Howitt 1984). Neostigmine can be administered to small and large animals by slow IV injection at the dose of 0.022 mg/kg. It should be remembered that cholinesterase inhibitors will cause intensification of ACh activity at both muscarinic and nicotinic receptors. Atropine (0.04 mg/kg) should be administered prior to or in conjunction with neostigmine to circumvent the muscarinic effects of the latter drug (Klein et al., 1983; Jones 1985). Care should be taken to ensure that paralysis does not recur after antagonism by neostigmine; additional injection of neostigmine may be required.

Because cardiovascular complications occasionally occur after treatment with atropine and neostigmine, new ideas have evolved in management of persistent paralysis in patients treated with nondepolarizing neuromuscular blocking drugs. These include substitution of quaternary ammonium muscarinic antagonists in place of atropine (to avoid potential CNS effects of atropine) and substitution of pyridostigmine and edrophonium for neostigmine. Pyridostigmine in combination with propantheline or glycopyrrolate, e.g., produced less abrupt changes in heart rate than combined therapy of either atropine-neostigmine or atropine-pyridostigmine. Pyridostigmine (0.05-0.08 mg/kg), a moderately long-acting drug, and edrophonium (0.2-0.4 mg/kg), a short-acting agent, when combined with either propantheline (0.03-0.06 mg/kg) or glycopyrrolate (0.004-0.006 mg/kg), were reported to produce a rapid and effective reversal of pancuronium-induced neuromuscular block in humans, with minimal changes in heart rate and almost no incidence of arrhythmias (Gyermek 1977). The clinical effectiveness of the above regimen in reversing neuromuscular paralysis produced by competitive agents other than pancuronium or in other species should be examined.

A new drug, 4-aminopyridine, was found to antagonize curare-induced neuromuscular block; however, this agent is not a cholinesterase inhibitor. Instead, it evokes release of ACh from the somatic nerve terminal. Advantages of 4-aminopyridine over cholinesterase inhibitors include longer duration of action without muscarinic side effects. Thus concurrent therapy with atropine-like drugs is unnecessary. The CNS excitatory effects of 4-aminopyridine limit its use in doses adequate to completely antagonize curare block. However, this agent markedly potentiates the anticurare activity of cholinesterase inhibitors. This combined therapy of low doses of 4-aminopyridine and a cholinesterase inhibitor has considerable potential application to clinical reversal of the nondepolarizing type of neuromuscular blocking agents (Miller 1979).

Neostigmine or other cholinesterase inhibitors should not be used in attempts to reverse the effects of a depolarizing agent (Sunew and Hicks 1978). Reliable chemical antidotes are not available for this group of agents. Artificial respiration may be required for a prolonged period. Injection of purified pseudocholinesterase preparation has been shown to hasten recovery from the effects of succinylcholine (Scholler et al. 1977).

Because of the small therapeutic index of neuromuscular blocking agents, their clinical use should always be supervised by qualified experienced personnel who are thoroughly familiar with the indications, limitations, hazards, and methods of administration of these highly active drugs.

INTRODUCTION TO DRUGS ACTING ON THE CENTRAL NERVOUS SYSTEM AND PRINCIPLES OF ANESTHESIOLOGY

EUGENE P. STEFFEY

Introduction to CNS Drugs
  Neuroanatomy and Neurophysiology
  Action of Drugs in the CNS
Principles of Anesthesiology
  Anesthetic Use
  Anesthesia Classified
  Basics of Clinical Anesthesia
  Evaluation of the Response to Anesthesia

Drugs that act in the central nervous system (CNS) are of fundamental importance to health care delivery. Some agents are administered to animals to directly improve their well-being. For example, without general anesthesia, modern surgery would not be possible. Some drugs alter behavior and improve animal-human interaction. They may induce sleep or arousal or prevent seizures. Drugs that act in the CNS are sometimes administered in an attempt to understand the cellular and molecular basis for CNS actions (i.e., physiology and pathophysiology) and/or identify the sites and mechanisms of action of other drugs. Finally, CNS actions of some drugs come as unwanted "side effects" when those drugs are used to treat conditions elsewhere in the body. For example, seizures may result from the injection of too much local anesthetic.

The purpose of this chapter is to, first, review principles of organization and function of the CNS. The intent is to lay a foundation from which later discussion on principles and applied aspects of CNS pharmacology can meaningfully follow. Behavior-altering drugs and anesthetics are routinely administered to animals by veterinarians and allied personnel. Appropriate use of these drugs is an important application of our knowledge of CNS pharmacology. Therefore, this chapter will conclude with a review of the principles of contemporary veterinary anesthesiology.

INTRODUCTION TO CNS DRUGS

NEUROANATOMY AND NEUROPHYSIOLOGY. The CNS consists of the brain and spinal cord. As opposed to the peripheral nervous system, which is mainly concerned with relaying sensory information to the brain and conveying signals to the effector organs, the CNS is involved with control and coordination of movement and higher functions such as consciousness and memory. A detailed discussion of neuroanatomy and physiology is beyond the scope of this chapter and is available elsewhere, but a brief review is in order. A great deal of the information to follow has been synthesized from more extensive reviews (Bradley 1989; Guyton and Hall 1996; Nicoll 1998; Bloom 1996; Cooper et al. 1996; Sihra and Nichols 1993; Unwin 1993).

The basic functional unit of the nervous system is the nerve cell, or neuron. The neuron has three parts: a cell body, a dendritic tree, and an axon. The CNS comprises billions of neurons, many of which are linked and form diffuse networks. Because of the complex arrangements of these transmission lines, an impulse may be (1) blocked in its transmission from one neuron to another, (2) changed from a single impulse into repetitive impulses, or (3) integrated with impulses from other neurons to result in highly intricate patterns of impulses in subsequent neurons (Guyton and Hall 1996).

Nerve impulses are transmitted from one neuron to the next via specialized structures called synapses. Synapses determine the path of spread of signals within the nervous system. For example, some synapses easily transmit signals from one neuron to another; others do it with more difficulty. Other areas of the nervous system can alter function, sometimes facilitating synaptic transmission by "opening" synapses for transmission and at other times "closing" them. Thus, synapses are junction points and as such are sites of focus for control of signal transmission. There are two types of synapses: the chemically mediated and the electrical synapses. The electrical synapse is characterized by channels that conduct impulses directly from one cell to the next. However, the vast majority of signal transmission in the CNS is via chemically mediated synapses. An important characteristic of chemically mediated synapses is that unlike the electrical synapse they always transmit signals in one direction. Transmission is initiated when the first neuron (i.e., the presynaptic neuron) releases a chemical substance known as a neurotransmitter, which impinges on the surface of the other cell (the postsynaptic neuron) (Fig. 9.1). Usually the cell body or dendritic region is the receiving end of the neuron, and the axon terminals are the transmitting end of the cell. However, other synaptic arrangements, such as axoaxonic and dendrodendritic, also exist.

Figure 9.2 shows the basic physiologic anatomy of the synapse. The presynaptic terminal is separated from the postsynaptic neural stroma by a synaptic cleft. Transmitter vesicles are located in the presynaptic terminal. These vesicles contain transmitter chemicals that when released either excite or inhibit postsynaptic neuronal functions by way of receptor proteins on the postsynaptic neuron.

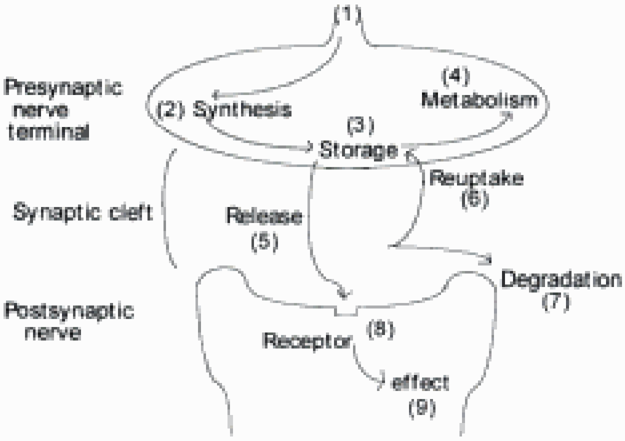

FIG. 9.1—Simplified schematic of steps in interneuron transmission of a nerve impulse. (1) Action potential propagated in the presynaptic nerve, (2) transmitter synthesis, (3) transmitter storage, (4) interneuron transmitter breakdown or inactivation, (5) transmitter release into the synaptic cleft, (6) transmitter reuptake into presynaptic terminal, (7) transmitter synaptic degradation, (8) transmitter attachment to postsynaptic receptor, and (9) receptor-induced increase or decrease in ionic conductance or altered cellular process.

The events involved in the release of transmitter from the presynaptic terminal are initiated by an impulse (action potential) that is propagated in the presynaptic fiber and travels to the synaptic terminal (Fig. 9.2). There are a large number of voltage-gated calcium channels at this location, and the action potential activates these channels (Sihra and Nichols 1993). Calcium ions then flow into the terminal. The rapid increase in intraterminal calcium concentration promotes the fusion of transmitter-containing synaptic vesicles with the presynaptic membrane. The transmitter is then released from the vesicles into the synaptic cleft and diffuses to receptors on the postsynaptic membrane. The amount of transmitter released is directly related to the number of calcium ions that enter the terminal.

Receptor proteins on the membrane of the postsynaptic neuron have two important components: a binding component (binds with the neurotransmitter) and an inophore component. The inophore component passes through the membrane to the interior of the postsynaptic neuron. There are two types of inophore components. One type is an ion channel. Membrane ion channels can be pictured as water-filled tunnels through the cell membrane and provide an aqueous route for specific types of ions to traverse the hydrophobic membrane interior. Cationic channels most often allow passage of sodium ions but sometimes potassium or calcium and serve to excite the postsynaptic membrane (i.e., excitatory transmitters open these channels). Anionic channels allow mainly chloride to pass through and are opened by inhibitory transmitters; open chloride channels inhibit neuronal function. Ion channels provide for rapid activation or inhibition of neuronal function. The other type of inophore component is a "second-messenger" activator; i.e., the component protrudes into the cell cytoplasm and activates substances within the neuron that

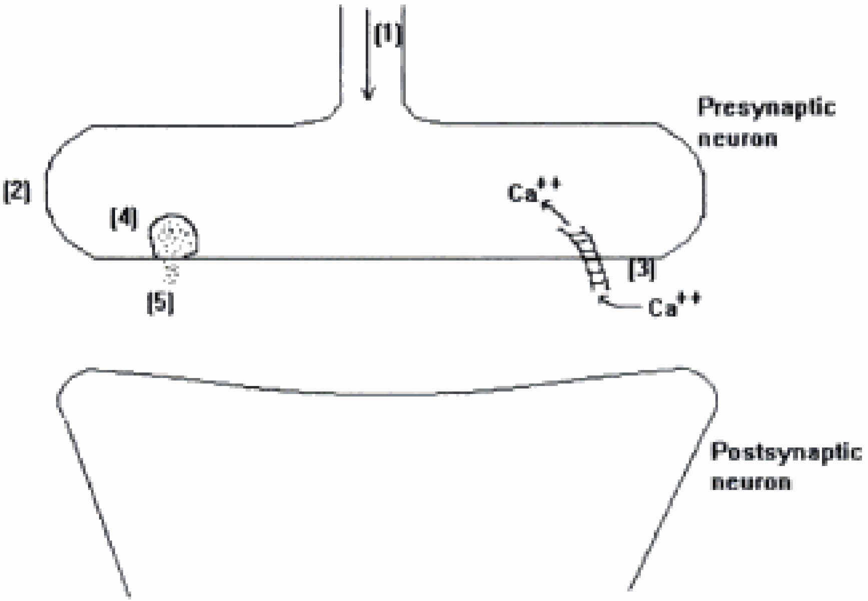

FIG. 9.2—Release of neurotransmitter at the synapse. The action potential (1) arrives at the nerve terminal (2) and stops here. It causes the opening of calcium channels (3) (voltage gated), allowing Ca^{++} to enter the presynaptic terminal. The Ca^{++} within the terminal catalyzes a reaction leading to liberation of transmitter (4) from the terminal's vesicles into the synaptic cleft (5).

TABLE 9.1—Summary of small-molecule neurotransmitters located in the CNS

Transmitter	Anatomic location in CNS	Receptor subtypes	Predominant postsynaptic action
Acetylcholine	Cell bodies at all levels	Yes	Excitatory (and inhibitory)
Monoamines			
Norepinephrine	Cell bodies in pons and brain stem	Yes	Excitatory (and inhibitory)
Dopamine	Cell bodies at all levels	Yes	Inhibitory
5-hydroxytryptamine (serotonin)	Cell bodies in brain stem and pons	Yes	Inhibitory (and excitatory)
Amino acids			
Gamma-aminobutyric acid (GABA)	Supraspinal interneurons involved in presynaptic inhibition	Yes	Inhibitory
Glycine	Spinal and brain stem interneurons	—	Inhibitory
Glutamate and aspartate	Relay neurons at all levels	—	Excitatory

Sources: Guyton and Hall 1996; Nicoll 1998; Bloom 1996; Cooper et al. 1996; Bradley 1989.

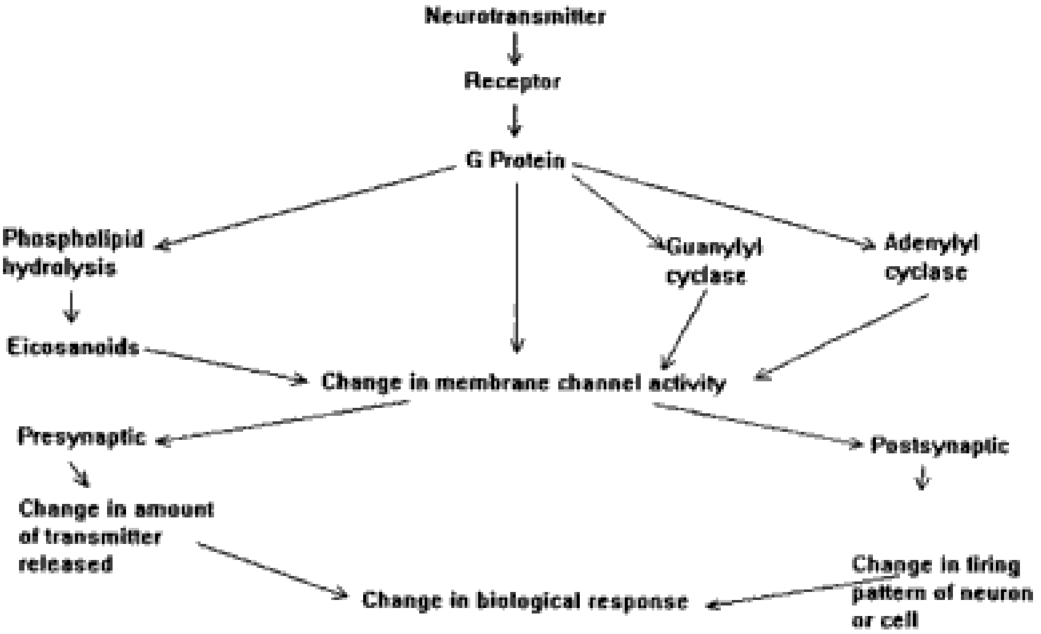
in turn serve as "second messengers" to alter cell functions. Unlike the results of ion channel activation by neuronal changes, the neuronal changes activated by a second-messenger system cause prolonged (i.e., seconds to months) neuronal effects. One of the most common types of second-messenger systems in neurons uses a protein complex known as G proteins.

Over 40 different neurotransmitter substances have been identified. They are usually classified into two major groups: small-molecule, rapidly acting transmitters (Table 9.1) and slowly acting, neuropeptide transmitters (Table 9.2) (Guyton and Hall 1996). Many of these transmitters are operational in the CNS. An alternative transmitter classification scheme has been proposed (Strange 1988) and is favored by some authors (Cooper et al. 1996). Further evidence may require that the more traditional classification presented here be modified.

TABLE 9.2—Examples of neuropeptide neurotransmitters located in the CNS

β Endorphin	Substance P
Vasopressin	Somatostatin
Oxytocin	Cholecystokinin
Growth hormone	Angiotensin II
Enkephalin	Neurotensin

Neurotransmitters in the CNS. The small-molecule, rapidly acting transmitters are the ones of most concern to us in this discussion (Table 9.1). They are synthesized in the cytosol of the presynaptic terminal and cause most of the responses in the CNS. Their actions on receptors usually occur within a millisecond or less after release. Afterward they either are destroyed (degraded) locally by enzymes, diffuse out of the cleft, or are absorbed by active transport back into



Neurotransmitter

FIG. 9.3—Synaptic transmission pathway. (From Cooper et al. 1996.)

transmitter vesicles (i.e., reuptake) (Fig. 9.1). The larger group of neurotransmitters comprises the neuropeptides (Table 9.2), which are very potent, slower to act, and present in much smaller quantities than the small-molecule transmitters. They are synthesized by ribosomes in the neuronal cell body. Some, such as the endorphins, will be discussed later in this and other chapters.

As noted above, the effect of the transmitters on the postsynaptic neuronal membrane is usually to increase or decrease conductance through ion channels; e.g., increased sodium conductance from outside the cell to inside causes excitation, and increased potassium (from inside to outside) or chloride (from outside to inside) conductance causes inhibition (Unwin 1993). At other times the transmitters stimulate receptor-activated enzymes that in turn change the intracellular metabolic processes. Many neuropeptides and biogenic amines act via this latter method. That is, the neurotransmitter (the "first messenger") links with receptor proteins of the postsynaptic membrane. The resultant conformational change occurring in the receptor protein enables the receptor to interact with a second element in the system, the G protein. The G protein in turn transduces the signal to an amplifying enzyme (a third component). This activity activates a "second messenger." The second messenger then interacts with various cellular processes to invoke the ultimate action (Fig. 9.3). Currently, three major biochemical cascades have been described as second messengers in the CNS. They are the adenylyl cyclase (cyclic AMP), guanylyl cyclase, and phospholipid hydrolysis (eicosanoid) systems (Cooper et al. 1996). The amines (Table 9.1) are an example of neurotransmitters acting (via cyclic AMP) in this general way.

Knowledge of the CNS sites at which given neurotransmitters operate and the degree of specificity by which such sites are affected is rapidly mounting, but in many cases a clear picture is not yet formed.

Characteristics of Some of the More Important Small-Molecule, Rapidly Acting Type of Neurotransmitters

ACETYLCHOLINE. Acetylcholine is widely distributed throughout the CNS. The mechanisms by which acetylcholine functions as a synaptic transmitter in the CNS are similar to those operant in the periphery (e.g., the neuromuscular junction). The transmitter is released from vesicles at the presynaptic terminal and diffuses across the synaptic cleft to act upon postsynaptic receptors. It is then inactivated via hydrolysis (acetylcholinesterase). As in the periphery, cholinergic receptors are of two classes: muscarinic and nicotinic. To date, five muscarinic receptors (M_1-M_5) are known (Caulfield and Birdsall 1998), and M_1 is abundant in the brain. They are coupled to G proteins and either act directly on ion channels or are linked to a variety of second-messenger systems (Cooper et al. 1996). Their effect is primarily to close K^+, Ca^{++}, or Cl^- channels depending on cell type, leading to either depolarization or hyperpolarization. In most regions of the CNS the effects of acetylcholine seem to be the result of an interaction with a mixture of nicotinic and muscarinic receptors (Bloom 1996). While most actions are believed to be related to postsynaptic receptors, it is known that presynaptic receptors for acetylcholine exist at many nerve terminals in the CNS. The function of these presynaptic terminals is to modulate release of neurotransmitter (Bradley 1989). Only relatively recently have nicotinic cholinergic receptors been identified in the CNS. Multiple subtypes are known (Kerlavage et al. 1987). There is as yet only limited evidence for a physiological role for nicotinic receptors in synaptic function in the mammalian brain (Role and Berg 1996). Recent review on muscarinic receptors are summarized in Caulfield and Birdsall 1998.

NOREPINEPHRINE. Like acetylcholine, the mechanisms by which norepinephrine functions in synaptic transmission in the CNS are very similar, if not identical, to those in the periphery. However, unlike acetylcholine, norepinephrine has an uneven distribution in the CNS, although the distribution is similar among most mammals. Two regions of the CNS that are most important in this regard are the locus ceruleus (caudal central gray matter of the brain stem) and the lateral and ventral trigeminal regions of the medulla (reticular formation). From neurons arising in these locations, axons innervate target cells in cortical, subcortical, and spino-medullary fields.

Norepinephrine mechanisms are considered important in the control of sleep and wakefulness, mood and emotional behavior, and temperature, among other functions. In most but not all of these areas norepinephrine probably activates excitatory receptors.

Both α and β adrenoreceptors are present in the CNS, and as in the periphery their actions are further differentiated into α_1 and α_2 and β families, each with their own further subtypes. Both pre- and postsynaptic receptors are present. Norepinephrine is secreted by most of the postganglionic neurons of the sympathetic nervous system. The α_2 family is of particular investigative interest at present, and our knowledge in this area is rapidly increasing. More on this subject is presented later in this volume (see also Ruffolo et al. 1993; Limbird 1988).

EPINEPHRINE. The direct influence of epinephrine in CNS synaptic transmission was recognized only relatively recently. Epinephrine-containing neurons are found in the reticular formation of the medulla. The physiological properties of CNS neurons using epinephrine as a neurotransmitter are poorly understood.

DOPAMINE. In the CNS dopamine is a major neurotransmitter in addition to its role as a precursor in the synthesis of norepinephrine. It is distributed heterogeneously throughout the CNS. The largest concentration of dopamine in the brain is in the basal ganglia and the limbic system. Dopamine in the CNS is linked to fine control of movement, to disturbances of behavior, and to the hypothalamic-pituitary endocrine system. Dopamine has primarily an inhibitory function.

Before 1992 two classes of dopamine receptors were recognized as distinct molecular entities, utilizing different messenger systems and having different distributions in the brain. Dopamine-1 (D_1) receptors are located postsynaptically and activate adenylyl cyclase as a second messenger and increase levels of cyclic AMP. Dopamine-2 (D_2) receptors are located both pre- and postsynaptically and inhibit or have no effect on the synthesis of cyclic AMP. Molecular biological approaches have identified additional forms of the dopamine receptor. Results indicate that the D_1 and D_2 subtypes represent families of dopamine receptors. For example, subtypes D_3 and D_4 receptors are similar in action to D_2 and are prototypic of G-protein-coupled receptors that inhibit adenylyl cyclase. The D_5 receptor is similar to D_1; it couples to the G protein and activates adenylyl cyclase. The D_3 receptor is of particular interest because of its hypothesized role as a therapeutic target for treatment of schizophrenia and drug abuse in humans (Levant 1997; Missale et al. 1998).

5-HYDROXYTRYPTAMINE. This neurotransmitter is also known as 5-HT or serotonin and has strong inhibitory actions. It inhibits pain pathways in the spinal cord and is believed to help control behavioral mood. Inhibition results from membrane hyperpolarization caused by an increase in K^+ conductance.

The neurotransmitter 5-HT is present in highest concentration in blood platelets and the gastrointestinal tract. Most of the 5-HT-associated neuronal pathways originate from the pons and upper brain stem regions and project to many brain and spinal cord areas. Multiple distinct 5-HT receptors and subtypes have been identified in the brain (14 according to Bloom 1996). Proposed CNS regulatory functions of 5-HT-containing neurons include sleep and wakefulness, mood and emotion, temperature, and appetite and neuroendocrine control. Presynaptic autoreceptors on 5-HT terminals have been found in the brain. Stimulation of these receptors inhibits the release of more transmitter. Presynaptic 5-HT receptors have also been found on nerve terminals that release other neurotransmitters, e.g., dopamine (Bradley 1989).

HISTAMINE. Only recently has evidence been accumulated to support the hypothesis that histamine functions as a neurotransmitter in the brain (Schwartz et al. 1991). Most of these neurons are located in the posterior hypothalamus. Three subtypes of histamine receptors have been described (H_1, H_2, and H_3), and all are found in peripheral tissues and brain (Bloom 1996; Hill et al. 1997). The function of this system in the brain is uncertain but it is thought to be involved in the regulation of arousal, temperature, and vascular dynamics.

AMINO ACIDS. High concentrations of certain amino acids are contained in the CNS. From a quantitative standpoint they are likely the major transmitters in the mammalian CNS. They fall into two categories: (1) the predominantly inhibitory, neutral acids, γ-aminobutyric acid (GABA) and glycine, and (2) the predominantly excitatory, acidic acids, glutamate and aspartate. They are all extremely potent modifiers of neuronal excitability.

GABA. In 1954, γ-aminobutyric acid (GABA) was first proposed as an inhibitory neurotransmitter in the mammalian CNS. It is distributed widely in the CNS; however, its concentration varies in different regions, with the greatest concentrations found in the basal ganglia, hippocampus, cerebellum, and hypothalamus in the brain and in the substantia gelatinosa of the dorsal horn of the spinal cord. Large concentrations are also found in the retina. In both the brain and the spinal cord, many of the GABA-containing neurons are short interneurons. GABA has a major functional role in the control of spinal and cerebellar reflexes. GABA is involved in the induction of convulsions and may also be important in anxiety states. It is considered the major inhibitory transmitter receptor in the CNS. Stimulation causes a shift in postsynaptic membrane permeability to inorganic ions, primarily chloride. This results in hyperpolarization of the receptive neuron in the case of postsynaptic inhibition or depolarization with presynaptic inhibition.

There are two major types (families) of GABA receptors (Barnard et al. 1998): GABA_A (Bowery 1989) and GABA_B (Olsen and Tobin 1990; Bowery 1993). The types are pharmacologically separate and have different second-messenger mechanisms and different locations within the CNS. Both receptor families have pre- and postsynaptic locations.

GABA_A is the most prevalent family. The GABA_A receptor is a ligand-gated Cl^- ion channel that opens after release of GABA from presynaptic neurons. Classes of subunits are described as α, β, γ, δ, ε, π, and ρ. Many neuroactive substances (e.g., alcohol, barbiturates and benzodiazepines) facilitate the effects of GABA_A on Cl^- conductance. Further information is given in Sieghart 1995 and Barnard et al. 1998.

The GABA_B receptor acts via G protein to increase conductance in K^+ channels. The functional role of GABA_B receptors in the CNS is poorly understood.

GLYCINE. Glycine appears to serve as the inhibiting transmitter between spinal interneurons and motor neurons. Like GABA it acts by increasing conductance of Cl^-. Its actions are poorly understood but seem restricted to the spinal cord, lower brain stem, and retina. Glycine subtypes have been described but their functional significance is not known.

GLUTAMATE AND ASPARTATE. Glutamate and aspartate occur in uniquely high concentrations in the brain. Glutamate is considered the primary excitatory transmitter in the brain and spinal cord; it is estimated to be responsible for 75% of the excitatory transmission in the brain. Aspartate is also likely a principal excitatory transmitter throughout the CNS but its function has been less well studied.

Glutamate receptors are classified as two types: metabotropic (G-protein-coupled) receptors and ionotropic (ligand-gated ion channel) receptors. The ion-gated receptors resemble GABA_A receptors and are further divided into three types named for the cogeners of glutamate to which they respond. These are the kainate receptors, the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors, and the *N*-methyl-D-aspartate (NMDA) receptors. The kainate and AMPA receptors are simple ion channels that permit Na^+ influx and K^+ efflux, while the NMDA receptor permits passage of Ca^{++} (Kaczmarek et al. 1997).

In recent years the NMDA receptor has become a major focus of attention because it may be involved in a wide range of both neurophysiological and pathological processes. For example, actions of these receptors are very selectively blocked by the dissociative anesthetics ketamine and phencyclidine, which enter and block the open ion channel. There are considerable potential therapeutic benefits from this action, e.g., inhibition of epilepsy and the neurotoxic effects of brain ischemia.

NITRIC OXIDE. Nitric oxide (NO) occurs in regions of the brain that are responsible for long-term behavior and memory. It differs from other small-molecule transmitters in that it is not preformed and stored in vesicles in the presynaptic terminal but instead is synthesized nearly instantly as needed and then rapidly diffuses out of the terminal. It also usually does not alter membrane potential but acts by changing intracellular functions that in turn modify neuronal excitability.

NEUROPEPTIDES. The peptides differ in many ways from the neurotransmitters thus far reviewed. They are greater in number of known substances, present in smaller quantities, and far more potent. Their synthesis is directed by messenger RNA and is much more complicated than that of the classic neurotransmitter, taking place in ribosomes. The prohormone so produced is larger than the ultimate transmitter and biologically inactive. It is packaged into vesicles in the smooth endoplasmic reticulum and transported to the nerve terminal for later release by a calcium-dependent (like the classic transmitter) process. After release, the peptides are probably not recycled but inactivated by enzymatic breakdown.

The neuropeptides are thought to act on specific receptors; however, few have actually been identified or characterized. Like other neurotransmitters, some of the postsynaptic effects are probably mediated by direct alteration of ion channel conductance or indirect regulation of ion channels via second-messenger systems (Cooper et al. 1996). Current thought also includes the possibility that they act in concert with the small-molecule neurotransmitters discussed above. That is, in many cases the neuropeptides are present in the same terminals as the small-molecule neurotransmitters and are released together with them. Investigators thus speculate that the action of neuropeptides may be to simply expand the armamentarium of the messenger molecules to enable transmission of an enriched message that requires more than one type of transmitter for its full effect; that is, the peptide embellishes what the primary transmitter "seeks" to accomplish.

For example, the action of the peptide might be to strengthen or prolong the primary transmitter actions (Cooper et al. 1991).

Many peptide families acting as neurotransmitters have been characterized to date (Table 9.2), with more surely to come. Only two of these will be briefly introduced here as examples.

SUBSTANCE P. Substance P has been known for more than six decades, being initially identified in the brain and intestine. The primary effect of substance P release in the brain is an excitatory action on dopaminergic neurons (Bradley 1989). Prolonged duration of action is a prominent finding associated with substance P. It is commonly accepted that it is the neurotransmitter released by primary afferent nerve fibers in the dorsal horn of the spinal cord and mediates sensation of noxious stimuli.

OPIOID PEPTIDES. These peptides have agonist activity at opiate receptors. An opiate is a substance derived from the opium poppy that has analgesic properties, e.g., morphine. An endorphin is any chemical substance naturally formed in the living animal (i.e., endogenous) that exhibits pharmacological properties of morphine. The endorphins are transmitters at a number of synapses in the pain-modularity mechanism, such as those related to the periaqueductal and periventricular gray matter of the CNS. The term *endorphin* actually encompasses what has become a family of opioid peptides currently viewed as comprising three branches: the pro-opiomelanocortin-derived peptides (e.g., β endorphin, the most potent of the natural opioids), the proenkephalin-derived peptides (e.g., Met-enkephalin and Leu-enkephalin), and the prodynorphin-derived peptides (e.g., dynorphin). The peptides derived from proenkephalin and prodynorphin are widely distributed throughout the CNS and often found in the same area, whereas those derived from the pro-opiomelanocortin branch have more restricted distribution, e.g., anterior and intermediate lobes of the pituitary gland. Current thought is that likely the shorter-acting enkephalins are neurotransmitters, and the longer-acting peptides like β endorphin have more of a modulating (hormonal) effect on the CNS. The enkephalins and β endorphins are involved in mediating analgesia. Subtypes of opiate receptors are generally recognized and include mu (μ), delta (δ), and kappa (κ). It is presently unclear whether or not a fourth type, the sigma (σ) receptor, is actually a true opiate receptor. There are also some data to indicate that μ (Pasternak and Wood 1986), δ (Wild et al. 1991; Negri et al. 1991), and κ (Rothman et al. 1990; Unterwald et al. 1991) receptors consist of multiple subtypes.

The μ receptor is thought to be the site at which analgesia is mediated in the brain. Morphine and β endorphin are potent agonists (enkephalins less so) of receptor activity, and naloxone is a potent antagonist of receptor activity. Stimulation of this receptor is also associated with respiratory depression, dependence, miosis, and decreased gastrointestinal propulsive motility. The δ receptor is strongly influenced by Leu-enkephalin, followed in order by Met-enkephalin, β endorphin, and morphine. In addition to analgesia these receptors are thought to mediate behavioral and sedative actions. The κ receptor is stimulated by dynorphin and mediates spinal analgesia but also causes dysphoria.

ACTION OF DRUGS IN THE CNS

Sites of Drug Action. Drug action in the CNS may be specific or nonspecific. Many drugs produce their effects by specifically modifying some step or mechanism in the chemical synaptic transmission of nerve impulses that was reviewed above (Fig. 9.1). For example, nerve impulse conduction can be prevented by applying local anesthetic to the nerve fiber, as occurs with epidural anesthesia. Synaptic transmission can be blocked or depressed at the presynaptic site by halting transmitter synthesis or storage. For example, reserpine interferes with the intracellular storage of monoamines and thereby limits their availability for release from the presynaptic cell terminal. Other drugs increase the release of transmitter (e.g., amphetamine), thereby causing a heightened (in this example, stimulant) response. Drugs may affect the reuptake (e.g., cocaine) or degradation (e.g., physostigmine) of drugs once they are released into the synaptic cleft. On the postsynaptic membrane drugs may act like the neurotransmitter on the receptor (e.g., opioids) or block receptor function at the level of the receptor or affect further transduction of the signal from the receptor (i.e., ion channels, enzyme systems, etc.).

On the other hand, some drugs are nonspecific in nature; i.e., a drug may affect many different target cells by diverse or poorly understood mechanisms. The inhaled anesthetics represent one such class of CNS drugs.

Blood-Brain Barrier. The boundary between the blood and tissues of the CNS is less permeable to large, water-soluble, and/or ionic molecules than that between blood and other tissues. The barrier that limits the penetration into the brain of hydrophilic substances like dissociated acids, bases, and proteins is known as the blood-brain barrier and has important pharmacological characteristics. The barrier exists both in the brain tissue capillaries and in the choroid plexus (i.e., the blood-cerebrospinal fluid barrier) and is created by the uniquely tight junctions between the brain's capillary endothelial cells or the epithelial cells of the choroid plexus and by the close association to capillary walls of glial cells. The barrier, however, is not absolute. Water, carbon dioxide, oxygen, and most lipid-soluble substances like anesthetics freely pass through cell membranes and gain entrance to the brain. However, the blood-brain barrier makes it very difficult to achieve effective concentrations of non-lipid-soluble drugs in the cerebrospinal fluid or parenchyma of the brain.

A selective active-transport mechanism is available for some substances. Recent evidence indicates that both the choroid plexus and the brain parenchymal capillaries have separate, specific, carrier-mediated transport mechanisms to transfer micronutrients (e.g., vitamins), macronutrients (e.g., glucose, amino acids), ions, and certain other substances between the blood and the extracellular space of the brain and cerebrospinal fluid (Spector 1990). Several types of carrier-mediated transport systems exist in plasma membranes and other parts of the cell. Water-soluble and ionic substances must use carrier mechanisms on each side of the cell to penetrate the brain parenchyma. These systems are broadly classified into three groups: (1) active transport, (2) facilitated diffusion, and (3) endosomal transport, in which substances are taken up by an energy-requiring system into endosomal sacs and transported into or out of the cell via these sacs.

PRINCIPLES OF ANESTHESIOLOGY

Anesthesiology is defined as the art and science of administration of anesthesia. The term also describes a clinical specialty of medicine (including veterinary medicine) that emerged during the early 1900s when a few physicians began devoting full time to the clinical administration of anesthetics. Anesthesiology was officially recognized as an organized specialty in medicine with the establishment in 1938 of a peer-certifying body of physicians, the American Board of Anesthesiologists (ABA). The ABA was an affiliate board of the American Board of Surgery and in 1941 became an independent board. In addition, in 1940 a section of anesthesiology was formed within the American Medical Association. In 1975 the American College of Veterinary Anesthesiologists was officially recognized by the American Veterinary Medical Association as the body to certify veterinarians as specialists in veterinary anesthesia. Broader summaries of the development of anesthesiology are available elsewhere (Smithcors 1971; Vandam 1994). The central role of the anesthetist is (1) to apply methods to minimize or eliminate pain, relax muscles, and facilitate patient restraint during surgical, obstetrical, and other medical, diagnostic, and therapeutic procedures and (2) to monitor and support life functions in patients during the operative period as well as in critically ill, injured, or otherwise seriously ill patients. The skills and knowledge that have developed in the field have extended the clinical practice of anesthesiology into intensive care, cardiac and pulmonary resuscitation, and the control of pain problems unrelated to surgery. The word anesthesia is derived from the Greek for "insensible" or "without feeling." The word does not necessarily imply loss of consciousness. In the realm of veterinary anesthesiology, anesthesia and anesthetics are used for a variety of reasons (Table 9.3).

TABLE 9.3—Use of anesthetics in animals

- Elimination of sensibility to noxious stimuli
- Humane restraint (e.g., protect animal, facilitate diagnostic or surgical procedure)
- Technical efficiency (e.g., protect personnel, facilitate diagnostic or surgical procedure)
- Specific biomedical research tool (e.g., sleep time)
- Control of convulsions
- Euthanasia

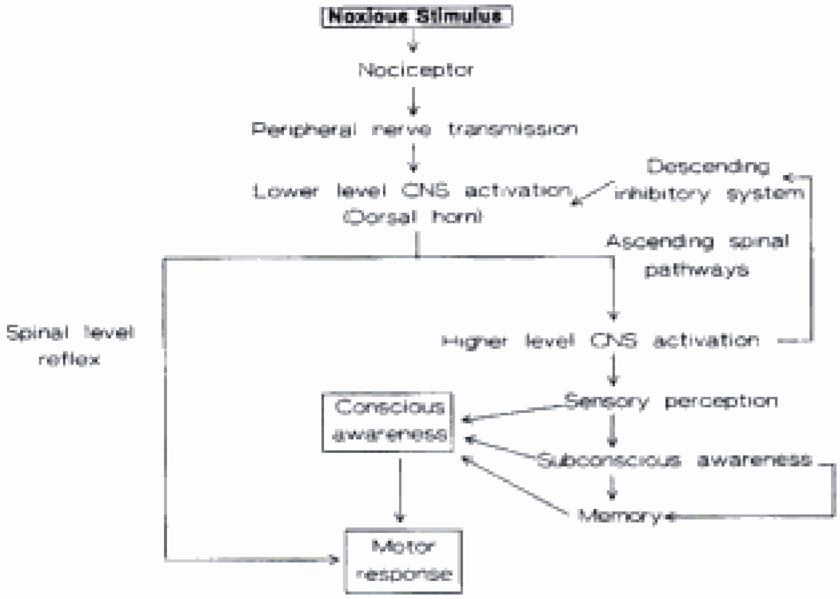
ANESTHETIC USE

Perception of Noxious Stimuli (Pain). Prevention of the perception of a noxious stimulus during surgery is the primary justification for anesthesia. A noxious stimulus is defined as a stimulus that is potentially damaging to body tissue. Nociception has no emotional or perceptional connotation. The stimulus triggers a reaction in an animal, including the feeling of pain in humans (Bonica 1990). Pain is an unpleasant sensory and emotional experience; it is a perception, not a physical entity. The perception of pain depends on a functioning cerebral cortex. The concept of pain includes several interdependent dimensions: the sensory/discriminative and motivational/affective.

It is not the intent to sidetrack here into semantic issues or to belabor what are to some fine points, but it is necessary for completeness to stress that contemporary reasoning holds that pain is a subjective response in conscious human beings. When considering "pain" in animals, it is important to recognize that our knowledge of pain in animals is largely inferential. We approach the subject with "the tacit assumption . . . that stimuli are noxious and strong enough to give rise to the perception of pain in animals if the stimuli are detected as pain by human beings, if they at least approach or exceed tissue damaging proportion and if they produce escape behavior in animals" (Kitchell and Erickson 1983).

CLASSICAL APPROACH TO MECHANISMS OF PAIN. Before further discussion of methods by which insensitivity is produced, it is helpful to briefly review the mechanisms whereby an individual becomes aware of and reacts to a noxious stimulus (Fig. 9.4). This inclusion here is justified on the basis that knowledge of these mechanisms offers the clinician targets for single or multiple attacks in an attempt to abolish or minimize pain.

Acute pain that is provoked by disease or injury (planned or unplanned) is the net effect of many interacting and complex anatomic paths and physiological mechanisms. The stimulus excites a specialized receptor organ, the nociceptor. Nociceptors are distributed throughout the body but are frequently grouped as somatic (cutaneous, muscle, bone, joint, fascia) or visceral. Nociceptors are located at the termination of free nerve endings of small poorly myelinated or nonmyelinated A-delta and C afferent nerves. The nociceptors transduce the stimuli into nociceptive impulses that are



Noxious Stimulus

transmitted to the CNS. Impulses that originate from areas below the head are transmitted via fibers that synapse with interneurons or second-order neurons in the dorsal horn of the spinal cord. Impulses from the head travel via fibers within the cranial nerves to the medulla, where they synapse with neurons in the trigeminal nuclei (medullary dorsal horn). In the spinal cord, the signal is subjected to a variety of potential modulating influences in the dorsal horn. For a long time the dorsal horn was considered to perform simply as a relay station. More recent evidence indicates it contains an incredibly complex circuitry and rich biochemistry that permits not only reception and transmission of nociceptive impulses but also a large degree of signal processing. After being subjected to these modulating influences, some of the impulses may then stimulate somatomotor and preganglionic sympathetic neurons and provoke nocifensive reflex responses. Nociceptive impulses also activate other neurons making up the ascending systems that pass to the brain stem and brain. Supraspinal systems that are probably involved in processing nociceptive information to progressively higher levels of awareness include the reticular formation, limbic system, hypothalamus, thalamus, and cortex.

Activation of the reticular formation results in abrupt awakening, diffuse alertness, and initiation of protective homeostatic responses. In turn, affective (emotional) alertness is obtained through cortical arousal. The animal is now fully knowledgeable regarding the cause and strength of the noxious stimulus and its relationship to the environment. The animal in turn reacts with a coordinated response.

For more detailed information the reader is referred to Bonica 1990, from which much of this summary has come, Willis 1985, and Wall and Melzack 1994.

Immobility. Although the primary reason for anesthetic delivery is to render the animal insensible to pain, restraint and technical efficiency are also long-recognized important considerations. Although viewed as an extreme in approach today, Alexandre Liautord, a Frenchman, noted in his 1892 *Manual of Operative Veterinary Surgery:* "In veterinary surgery, the indication for anesthesia has not, to the same extent as in human, the avoidance of pain in the patient for its object, and though the duties of the veterinarian include that of avoiding the infliction of *unnecessary* pain as much as possible, the administration of anesthetic compounds aims principally to facilitate the performance of the operation for its own sake, by depriving the patient of the power of obstructing, and perhaps even frustrating its execution, to his own detriment, by the violence of his struggles, and the persistency of his resistance. To prevent these, with their disastrous consequences, is the prime motive in the induction of the anesthetic state" (quoted in Smithcors 1971). More in keeping with contemporary thought are the words of George H. Dadd written in 1854 in *The Modern Horse Doctor:* "We recommend that, in all operations of this kind, the subject be etherized, not only in view of preventing pain, but that we may, in the absence of all struggling on the part of our patient, perform the operation satisfactorily, and in much less time after etherization has taken place than otherwise. So soon as the patient is under the influence of that valuable agent, we have nothing to fear from his struggles, provided we have the assistance of one experienced to administer it" (quoted in Smithcors 1971). Many of these same clinical principles can and should also be applied directly to the research environment.

2. General anesthesia: state of controlled, reversible CNS depression (including unconsciousness) produced by one or multiple drugs
   a. Injectable
   b. Inhalation
   c. Balanced

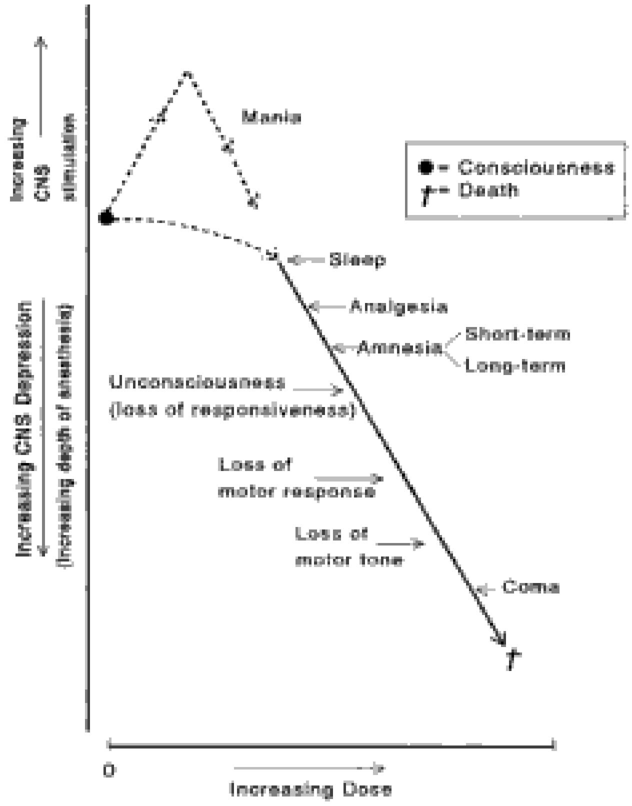

FIG. 9.5—The anesthetic continuum as viewed clinically in a healthy subject.

ANESTHESIA CLASSIFIED. Anesthesia is produced by both chemical (i.e., drugs) and physical (e.g., sensory nerve destruction) means. Anesthetic drugs are frequently classified according to their route of administration (Table 9.4). Some drugs are only suited for common delivery via one route, e.g., the inhalation anesthetics, while many of the injectable agents may be administered in a variety of different manners depending on the drug and the desired end point of effect.

Local and Regional Anesthesia. Anesthetics are also classified according to the region of the body influenced (Table 9.5). For example, a local anesthetic is administered, usually to conscious or mildly sedated animals, to desensitize a localized or regional area of the body. It is deposited in close proximity to a nerve membrane, causing nerve conduction blockade.

General Anesthesia. General anesthesia is a condition induced by pharmacological or other means that results in controlled, reversible CNS depression. It is true that some drugs in the process of producing anesthesia cause excessive stimulation and activity in the brain, but all anesthetic agents ultimately reduce and stop electrical activity in the brain and decrease brain oxygen consumption. On this basis it is proper to characterize anesthetic agents as CNS depressants.

Basic elements of general anesthesia in humans in addition to reversibility include loss of awareness (unconsciousness), no recall of events at the conscious level (amnesia), conscious insensitivity to pain (analgesia), and muscle relaxation and diminished motor response to noxious stimulation. In recent years the importance of minimal autonomic nervous system response to noxious stimulation has been also emphasized in clinical applications.

General anesthesia has traditionally been considered a dose-related continuum of a series of events passing into each other (Fig. 9.5), from alert wakefulness through lethargy and drowsiness (sedation), unconsciousness (with and without somatic and visceral response to external stimuli), coma, and death. The wakefulness to coma series implies progressive loss of higher CNS (cortical) function followed by depression of brain stem functions. While portions of this scheme have been challenged (Winters et al. 1967; Winters et al. 1972), its use is generally acceptable and offers a convenient method to set the stage for further discussion of principles of general anesthesia.

Techniques of General Anesthesia. General anesthesia is pharmacologically induced and maintained in animals via one of two general methods. The oldest approach, which is still widely used in certain animal applications, is the single-agent technique. With this technique, an agent such as pentobarbital, thiopental, or ketamine (or perhaps two agents such as xylazine and ketamine given simultaneously or in close time proximity) is administered at sufficient dose to provide the complete spectrum of characteristics of general anesthesia. This method is simple but may be more life threatening, especially under adverse circumstances, including animal ill health. Because *all* anesthetic agents have some undesirable effects when used alone, modern anesthetic practice increasingly involves the use of combinations of drugs. This technique is known as *balanced anesthesia*. With this technique, multiple drugs in low dosage are used, each drug for a specific purpose. The ultimate intent is to take advantage of the desirable features of selected drugs while minimizing their potential for harmful depression of homeostatic mechanisms. This technique is especially advantageous when used with physiologically compromised individuals. An example of such an approach is the combined use of a low dose of a hypnotic-sedative drug for unconsciousness and amnesia, an opioid for profound analgesia with little cardiovascular insult, a neuromuscular blocking drug for muscle relaxation, and intermittent positive pressure ventilation with oxygen to facilitate respiratory gas exchange in the face of total skeletal muscle paralysis. Unfortunately, the balanced technique is complex, and inexperienced or careless use of a drug combination may aggravate undesirable drug actions and/or other common difficulties encountered by the anesthetist.

Mechanism of Action Causing General Anesthesia. There have been many attempts to explain the mechanism of general anesthesia at a molecular level. Three simple observations limit possible explanations. The rate at which anesthesia can be induced and wakefulness resumed effectively rules out long-term biochemical events and focuses attention on drug-induced alterations of short-term biochemical events. In addition, the diverse chemical structures of anesthetic agents also pose a problem in arriving at a common theory of action. For example, anesthetic drugs range from inert gases such as xenon, relatively simple inorganic (nitrous oxide) and organic (chloral hydrate and chloroform) compounds, to progressively more complex molecules such as pentobarbital, ketamine, and alphaxalone (Fig. 9.6). The absence of a common chemical structure reduces the possibility of a specific-receptor-mediated action. Finally, explanation of their anesthetic action must in some way be linked with their ability to cause superimposed selective and specific anesthetic "side effects," such as reductions in myocardial contractility.

An important neurophysiological action common to most general anesthetics is to depress both spontaneous and evoked neuronal activity in many regions of the brain. Actions exerted on synaptic transmission seem most sensitive, whereas nerve conduction is little influenced. Anesthetics may reduce synaptic transmission by interfering with neurotransmitter release from presynaptic nerve terminals, by altering reuptake of neurotransmitter after release, by altering binding of neurotransmitter to postsynaptic receptor sites, or by influencing ionic conduction following activation of postsynaptic receptors. At this point in time, ionic mechanisms thought to be involved are varied and the focus of extensive study. For example, barbiturates are known to act on the GABA-receptor-mediated chloride channel, and at least some of the inhaled anesthetics are reported to cause hyperpolarization of neurons via activation of potassium currents. In both examples there is a decreased ability to initiate action potentials; i.e., the cellular threshold for firing is increased (Bradley 1989; Halsey 1989; Koblin 1994).

A striking physiochemical characteristic of inhalation anesthetic drugs is their lipid solubility—a physical property shown to correlate best with anesthetic potency. This correlation is commonly referred to as the *Meyer-Overton rule* after the two individuals who independently (1899 and 1901, respectively) noted that the potency of anesthetics increased directly in proportion to their partition coefficient between olive oil and water (i.e., the concentration ratio of the agent in oil and water at equilibrium). Because inhalation anesthetic molecules are hydrophobic and therefore distribute to sites in which they are removed from aqueous environments, and because of the close correlation between potency and lipophilicity, it is theorized that these anesthetics act in the cell membrane lipid layer. It is thought that their presence distorts the membrane structure, which in turn causes occlusion of the pores through which ions pass, e.g., the sodium channel (this is the so-called membrane expansion theory) (Halsey 1989; Koblin 1994).

Although there is no pharmacologic antagonist to inhalation anesthesia, very high ambient pressure (e.g., 50–100 atmospheres of pressure) causes reversal of the anesthetic state. This observation is another important clue to the mechanism of anesthesia. Because pressure acts by reducing volume, the reversal of anesthesia with pressure suggests that an increase in lipid volume (i.e., less-orderly arrangement of the membrane lipid molecules and thereby a small volume expansion) is somehow involved in the process.

Unfortunately, the membrane expansion theory is not without its faults, and a unitary theory of narcosis (i.e., the thought that all anesthetics have a common mode of action on a specific molecular site) may not be achievable. However, popular dogma has been challenged with observations that suggest anesthetic drugs do act at specific sites (Firestone 1988). During the past 10–15 years there has been increasing evidence that specific neuronal membrane proteins that permit translocation of ions during membrane excitation are the primary targets for anesthetic action. Debate is ongoing whether at least inhalation anesthetics disrupt ion flow through membrane channels by an indirect action on surrounding lipids or via a second messenger

or alternatively whether they link directly to membrane channel proteins. Regardless, the molecular mechanism of action of general anesthetic drugs is still far from clear, and there is still much to learn regarding this phenomenon. Readers are referred elsewhere for more in-depth analysis of this topic (Halsey 1989; Firestone 1988; Albrecht and Miletich 1988; Franks and Lieb 1987; and especially Koblin 1994).

BASICS OF CLINICAL ANESTHESIA. A favorable anesthetic course begins with a good plan—a plan based on sound pharmacological and physiological principles. There is no rigid format. *No anesthetic technique is unequivocally the best for all animals under all circumstances.* Each plan is adapted to prevailing circumstances. Accordingly, appropriate anesthetic management requires a broad understanding of the physiology of bodily life support systems (e.g., respiratory, circulatory, central and autonomic nervous systems), the pathology and pathophysiology of the condition(s) necessitating anesthesia and surgery, the pharmacology and principles and techniques of administration of anesthetic and adjuvant drugs, and monitoring and support of vital organ function. The rationale that underlies the selection of an appropriate anesthetic protocol is outlined in Table 9.6.

Drug selection for anesthetic management is accomplished by considering the pharmacological requirements for the individual case, reviewing and selecting major drug classes that are appropriate for the specific needs, and then reviewing characteristics and selecting the specific drug(s) within the desired drug class(es). Frequently, the best drug and technique are those with which the clinician is most experienced; i.e., there is an art to the clinical administration of potent, life-threatening drugs such as those used in anesthetic management.

Drugs used in anesthetic management can be conveniently classified according to time frame of use: the preanesthetic, perianesthetic, and immediate postanesthetic periods.

TABLE 9.7—Goals for preanesthetic medication

1. Alleviate or minimize pain
2. Allay apprehension
3. Facilitate handling
4. Minimize undesirable reflex autonomic nervous system activity
    a. Parasympathetic
        i. Vagal nerve
        ii. Secretions: salivary, bronchial
    b. Sympathetic
        i. Arrhythmic
        ii. Arterial blood pressure alterations
5. Supplement general anesthesia
    a. Add to level of analgesia, sedation
    b. Reduce anesthetic requirement
6. Minimize undesirable postanesthetic recovery complications
7. Prevent infection
8. Continue treatment of intercurrent disease

Preanesthetic Period. Drugs are usually administered to animals (usually 15–45 minutes) before induction of general anesthesia. The primary aims of preanesthetic medication are to calm the animal, facilitate handling, and relieve preoperative pain. These along with secondary goals are listed in Table 9.7. Unfortunately, preanesthetic medication is not without its complications, which also must be considered in formulating the anesthetic management plan (Table 9.8). The concurrent use of two or three drugs is usually required to accomplish the desired preanesthetic conditions in the patient. These are selected from a variety of major drug classes (Table 9.9). The extent of drug combinations advocated by individuals attests to the variety of circumstances commonly encountered clinically and to the lack of agreement on optimal drug effects.

TRANQUILIZER-SEDATIVES. Tranquilizers (ataractics or neuroleptics) are frequently administered to animals to produce a calming effect, i.e., tractability or "chemical restraint." This group of drugs includes the phenothiazine, the butyrophenone, and the benzodiazepine subclasses. They are frequently used in combination with other preanesthetic drugs (e.g., opioids), because lower doses can be used than would be the case if each drug were used alone and the degree of sedation accomplished by the drug combination is often potentiated without causing further severe circulatory and respiratory depression.

    b. Interaction with anesthetic and other adjuvant drugs
2. Anti-analgesia
3. Prolonged sedation influencing recovery from anesthesia
    a. Prolonged recumbency
    b. Ataxia

TABLE 9.9—Major classes of drugs (and specific drug examples) commonly considered for preanesthetic medication

1. Tranquilizer-sedative
    a. Acepromazine
    b. Diazepam
    c. Midazolam
    d. Droperidol
    e. Azaperone
2. Hypnotic-sedative
    a. Pentobarbital
    b. Chloral hydrate
3. Opioid
    a. Agonist
        i. Morphine
        ii. Meperidine
    b. Agonist-antagonist
        i. Butorphanol
4. α_2-adrenergic agonist
    a. Xylazine
    b. Detomidine
    c. Medetomidine
5. Dissociative
    a. Ketamine
6. Commercially prepared combinations of sedating drugs
    a. Telazol (tiletamine + zolazepam)
    b. Innovar-neuroleptanalgesia (fentanyl + droperidol)
7. Parasympatholytic
    a. Atropine
    b. Glycopyrrolate

The phenothiazines have received widespread use for many years. Their potency facilitates easy administration, and favorable tranquilization is usually realized. They have antiarrhythmic, antihistaminic, and antiemetic effects that may be particularly desirable. The α_1-adrenergic blocking action of the phenothiazines is likely to be of special concern in some patients because it results in usually unwanted arterial hypotension.

The butyrophenones also have α_1-adrenergic blocking activity, but better cardiovascular stability accompanies their use compared to the phenothiazines. Largely on the basis of cost and the lack of broad-based, clear advantages, the butyrophenones are less frequently used for anesthetic management of veterinary patients than other drugs in the tranquilizer grouping.

Although representatives of the benzodiazepines are increasingly used with other drugs to induce and maintain general anesthesia, especially in some animals their use in the preanesthetic period is, like the butyrophenones, very limited. Pain and occasional erratic absorption after intramuscular injection are characteristic of some benzodiazepines (e.g., diazepam). Also, sedative actions in otherwise healthy animals are quite variable across animal species commonly encountered in veterinary practice. Sedation caused by benzodiazepines can be reliably reversed by a specific antagonist at least in some species.

HYPNOTIC-SEDATIVES. Drugs of this class, including the barbiturates and chloral hydrate, cause a dose-dependent spectrum of CNS depression, sedation, sleep, anesthesia, coma, and death. They produce minimal ventilatory and circulatory depression in sedative doses. Disadvantages of their use include a lack of analgesia and the absence of a specific antagonist. Use of drugs from this class have largely been replaced in the preanesthetic period by the α_2-adrenergic agonist drugs.

α_2-ADRENERGIC DRUGS. Drugs such as xylazine cause dose-related sedation and analgesia. They are widely used across species lines singly and in combination with, especially, opioids and dissociative agents. Bradycardia, mild arterial hypertension followed by more prolonged hypotension, hyperglycemia, and increased urine volume are commonly attendant effects. Direct antagonists of varying purity and effectiveness are now available.

OPIOIDS. Potent analgesia, sedation, and the absence of direct myocardial depression are important advantages of the use of opioids in the preanesthetic period. Patients with preexisting preoperative pain or who will require painful diagnostic or therapeutic procedures before anesthetic induction are likely candidates for opioid preanesthetic medication. Opioid premedication is also appropriate prior to anesthetic management techniques that use opioids as a predominant component (i.e., a balanced technique, see above). Predominant adverse effects of opioids when used prior to anesthesia include depression of medullary ventilatory control centers resulting in decreased responsiveness to carbon dioxide and in turn hypoventilation. Opioids commonly induce a vagotonic affect so heart rate may also be decreased to variable degrees depending on agent, dose, and animal species. In some species (e.g., the dog) opioids commonly cause CNS sedation, while in others (e.g., the horse) excitement or CNS arousal are predominant concerns. Opioid-induced vomition in some species (e.g., dog) may be wanted (e.g., a newly presented patient with a full stomach requiring anesthesia for a diagnostic or minor surgical procedure) or unwanted (e.g., risk of pulmonary aspiration of vomitus in elderly or depressed patients). They also decrease intestinal propulsive and ruminal activity.

DISSOCIATIVE DRUGS. Drugs such as ketamine reliably cause a state of somatic analgesia and sedation in some species (e.g., cat) and may be of benefit in special clinical situations (e.g., highly fractious animals under conditions of limited management choices). Its relatively wide margin of safety in otherwise healthy animals is of special benefit under conditions of limited patient control or knowledge base.

The most prominent disadvantage of its use is that, depending on dosage, this class of drugs may cause CNS arousal in some species (e.g., horse) leading to animal excitement or frank convulsions.

DRUG COMBINATIONS. Sometimes drug combinations are marketed to provide ready access to clinical benefits of two drugs while attempting to minimize their individual disadvantages. For example, Telazol® is a combination of tiletamine, a dissociative agent, and zolazepam, a benzodiazepine tranquilizer-sedative. The combination improves the reliability of the sedative properties of either drug used alone without adding extensively to further vital organ depression (e.g., cardiopulmonary depression). However, as a consequence of the fixed combination, a prolonged duration of effect may be an unwanted result.

Innovar® is a combination of a short-acting opioid (fentanyl) and a longer-acting butyrophenone tranquilizer (droperidol). Its commercial availability to the North American veterinary community has varied greatly in recent years. Its use in, especially, dogs and swine provides reliable sedation and potent analgesia, again with limited vital organ depression. Bradycardia is commonly an unwanted side effect but can be countered by the administration of an anticholinergic drug such as atropine. The different duration of actions of the two component drugs is an important aspect of redosing considerations.

PARASYMPATHOLYTIC (ANTICHOLINERGIC) DRUGS. The most common reason for administering drugs such as atropine or the more potent, longer-acting glycopyrrolate before induction of general anesthesia is to reduce upper-airway and salivary secretions (antisialagogue effect) and counteract reflex bradycardia occurring with, e.g., concurrent opioid use or certain surgical manipulations (e.g., ocular).

In years past it was routine to use anticholinergics as part of the premedication scheme. However, this is no longer so. Contemporary anesthetic drugs are much less irritating to the respiratory tract, minimizing the likelihood of excessive respiratory tract secretions, and in the absence of potent vagotonic preanesthetic drugs it is thought that heightened vagal tone is best treated just prior to its anticipated occurrence or at first sign of its presence. Sparing use of anticholinergic drugs reduces the risk of other unwanted effects such as tachycardia or reduced gastrointestinal motility. Avoidance of gastrointestinal stasis is of special importance in herbivorous animals, for whom preanesthetic gastrointestinal emptying is almost never desired or

TABLE 9.10—Major classes of CNS drugs (and examples) commonly considered for general anesthesia

1. Hypnotic-sedatives
   a. Ultrashort acting
      i. Thiopental
   b. Short acting
      i. Pentobarbital
2. Dissociatives
   a. Ketamine
3. Opioid
   a. Morphine
   b. Oxymorphine
   c. Fentanyl
   d. Alfentanil
4. Drug combinations
   a. Innovar
   b. Telazol
5. Others
   a. Guaifenesin
   b. Propofol
   c. Etomidate
   d. Saffan
6. Tranquilizer-sedatives*
   a. Benzodiazepines

*Never used alone.

accomplished. Mydriasis is another effect (e.g., of atropine) that is often undesirable because it confounds interpretation of some clinical signs of anesthesia and/or exposes the patient to potential retinal damage in some uncontrolled postanesthetic circumstances.

Anesthetic Period. The administration of anesthesia requires a combination of knowledge, skill, and ingenuity. The anesthetic drugs selected and their dose and method of delivery will largely depend on the animal, the facilities available, and the skill of the individual who will administer them.

General anesthetics are usually given by inhalation or injection; on rare occasions anesthetic drugs may be given orally or per rectum. More specific information on anesthetic delivery is given later in this volume and in Short 1987, Hall and Clarke 1991, and Andrews 1990.

Drugs of several classes of injectable agents (Table 9.10) are commonly used for general anesthesia. These are preferably given intravenously (IV); however, because of the varied circumstances associated with clinical conditions in veterinary medicine, the intramuscular (IM) route is also widely used. The IV route is the preferred means of inducing general anesthesia because anesthetic induction with the loss or reduction of many of the patient's life-protecting reflexes is consistently the most crucial maneuver in managing general anesthesia. The IV administration permits incremental dosing and thus titration of the level of anesthetic to a desired end point. This technique is often desired especially in critically ill patients or in unfamiliar circumstances because of the likelihood of unpredictable animal responses to a "routine" dose of drug. Drugs of a single class are used alone or in combination with other drugs listed in Table 9.10 (e.g., inhalation anesthetics and neuromuscular blocking drugs) to achieve suitable anesthetic conditions. Many of the drugs from the classes listed in Table 9.10 are also used at lower dosage for preanesthetic medication (Table 9.9).

The barbiturates likely continue as overall the most popular intravenous anesthetic for animals. They have universal (or at least nearly so) geographic and species application. Accurate information is not readily available but likely the dissociative class of drugs has become a close second choice in popularity to the barbiturates. For example, ketamine may be used alone in some species or combined with other drugs to produce a state that enables restraint and surgery and can be administered via a variety of routes, a decided advantage for fractious animals and/or treatment outside the controlled hospital environment.

Opioids in large doses are the basis for balanced anesthetic techniques for human patients—especially those patients with circulatory system instability or those undergoing cardiac surgery. This method is also applicable to some veterinary patients (e.g., dogs) and is presently used to varying degrees. An important point to keep in mind is that opioids, even in large doses, do not predictably produce unconsciousness, so other drugs are used concurrently to accomplish the individualized goals of general anesthesia. Also, some animal species (e.g., horses) are excited by even moderate (by comparison to other species, e.g., dogs) opioid doses.

Immediate Postanesthetic Period. The immediate postanesthetic period is also known as the anesthetic recovery period. It begins with the discontinuation of the administration of anesthetic drugs. Recovery of healthy animals from routine anesthetic techniques is usually, but not always, uneventful and routine. Circumstances such as compromised physical status and unfamiliar anesthetic techniques heighten the likelihood of recovery problems. The immediate goal of this period is the rapid return of the patient's independent, uncompromised ability to maintain normal respiratory and circulatory systems function and to return sensory and motor abilities to preanesthetic levels as soon as possible. Despite this overriding philosophy, when the needs of different species and circumstances are considered, the actual broad plan is less clear. For example, most of the contemporary inhalation anesthetics do not have potent or persistent analgesic properties at alveolar concentrations associated with awakening. The sooner a patient recovers following surgery, the sooner there is potential for pain and an uncomfortable situation for the patient. Consequently, the question arises, is it better for a patient to awaken quickly following surgery and then receive, as needed, analgesic drugs, or is it more desirable and beneficial for the patient to receive analgesic drugs toward the end of the anesthetic period and as a result have a slower recovery from general anesthesia and transition to sensation? The same therapeutic dilemma applies to the patient who may emerge from anesthesia excited and risk a particularly "stormy" recovery with attendant physical injury. The various combinations of drugs used in anesthetic management coupled with unique species characteristics make it impossible to describe here all of the patterns

TABLE 9.11—Hazards of the immediate postanesthetic period

1. Circulatory system complications
   a. Arterial hypotension
   b. Arterial hypertension
   c. Cardiac dysrhythmias
2. Respiratory system complications
   a. Hypoxemia
   b. Hypoventilation
3. Pain
4. Emergence excitement (physical trauma)
5. Hyperthermia/hypothermia
6. Vomiting
7. Delayed awakening

of recovery that occur and appropriate therapeutic schemes. In the end, individualized therapy is the most desirable plan.

Hazards of the recovery period that may require therapeutic intervention are listed in Table 9.11.

EVALUATION OF THE RESPONSE TO ANESTHESIA. Since very early in the history of general anesthesia attempts have been made to correlate observations of the effects of anesthetics with "depth" of anesthesia. To be able to define the depth of anesthesia is important for a number of reasons. For example, too little or too much anesthesia is a threat to life. Consequently, if one can determine the magnitude of anesthesia with reasonable accuracy, patient safety is improved and optimal operating conditions are facilitated for the health care providers. Furthermore, specific guidelines help the novice anesthetist provide appropriate anesthetic conditions. Finally, in investigative circumstances an accurate means for describing and comparing anesthetic levels within or between studies is essential so that we may account for the effects of the anesthetic in our overall understanding versus other variables that may be operant and of interest at the time of study. It would be very helpful to be able to precisely define the depth of anesthesia in every animal from moment to moment regardless of the anesthetic technique. Unfortunately, this is presently not possible, so we rely on estimates.

TABLE 9.12—A summary of the classical description of the four stages of general anesthesia

1. Stage I
   a. Stage either of analgesia, induction, and voluntary excitement or of analgesia and amnesia
   b. Period from beginning of induction to loss of consciousness
   c. Voluntary resistance to restraint and to anesthetic vapors
   d. In humans: loss or obtundation of pain sensation; mental facilities controllable throughout this stage but progressively depressed until unconsciousness
2. Stage II
   a. Stage of delirium, involuntary excitement, or uninhibited action
   b. Period from loss of consciousness to onset of automatic respiration
   c. In humans: dream stage
3. Stage III
   a. Surgical stage
   b. Period from onset of automatic respiration to respiratory arrest
   c. Subdivided into four planes of anesthesia:
      i. Plane I: light surgical
      ii. Plane II: moderate surgical
      iii. Plane III: deep surgical
      iv. Plane IV: excessive surgical
4. Stage IV
   a. Stage of respiratory paralysis or overdose
   b. Interval between respiratory and cardiac arrest

Source: Modified from Steffey 1983.

More than 50 years ago Guedel (Guedel 1920, 1927) published his classic description of the four stages of anesthesia (Table 9.12). The traditional classification is based on a progressive depression of a continuum of CNS function. Guedel extended the descriptions of earlier workers such as Plomley (1847) and Snow (1847) to divide the state of anesthesia into distinct "packages," each correlating with a particular set of physiological responses or reflexes, i.e., clinical signs. The organizational scheme (Table 9.12) includes four stages of anesthesia and subdivides the third stage into four strata (i.e., planes). Guedel's system has been prominent in pharmacology texts (including earlier editions of this text) and anesthesia texts for more than five decades. The concept is included here in abbreviated form because its importance in the discussion of fundamental principles of anesthesia is becoming more limited.

The classic signs and stages are partly recognizable with many general anesthetics (e.g., the barbiturates), but they are incomplete or are obscured when using modern anesthetics (e.g., ketamine) and/or techniques. It is important to remember that Guedel's description was based on his observation of the actions of diethyl ether administered to otherwise unmedicated human patients who were breathing spontaneously. This is a situation far different from contemporary practice, in which controlled mechanical ventilation is common and newer and multiple anesthetic and adjuvant drugs are an important part of the anesthetic plan. There are unique differences in the way different species react to conditions of general anesthesia that also must be taken into consideration. Because of diethyl ether's characteristics and the methods of delivery, the onset and "deepening" of anesthesia were slow. This situation facilitated a slow (relative to today's standards) unfolding. In addition, numerous physiological responses to anesthetics that are widely monitored today (Table 9.13) are not included in the classic description.

With the emergence of anesthetics such as ketamine and enflurane the concept that all anesthetics are depressants required reconsideration. Winters et al.

TABLE 9.13—Useful signs in clinical assessment of anesthetic depth

1. Cardiovascular system
   a. Heart rate and rhythm[a]
   b. Arterial blood pressure[b]
   c. Mucous membrane color
   d. Capillary refill time
2. Respiratory system
   a. Breathing frequency[a]
   b. Ventilatory volumes (tidal and minute ventilation)[a]
   c. Character of breathing[a]
   d. Arterial or end-tidal CO_2 partial pressure[b]
3. Eye
   a. Position and/or movement of eyeball[b]
   b. Pupil size[a]
   c. Pupil response to light
   d. Palpebral reflex
   e. Corneal reflex
   f. Lacrimation
4. Muscle
   a. Jaw or limb tone[a]
   b. Presence or absence of gross movement[a]
   c. Shivering or trembling[a]
5. Miscellaneous
   a. Body temperature
   b. Laryngeal reflex[a]
   c. Swallowing[a]
   d. Coughing[a]
   e. Vocalizing[a]
   f. Salivating
   g. Sweating
   h. Urine flow

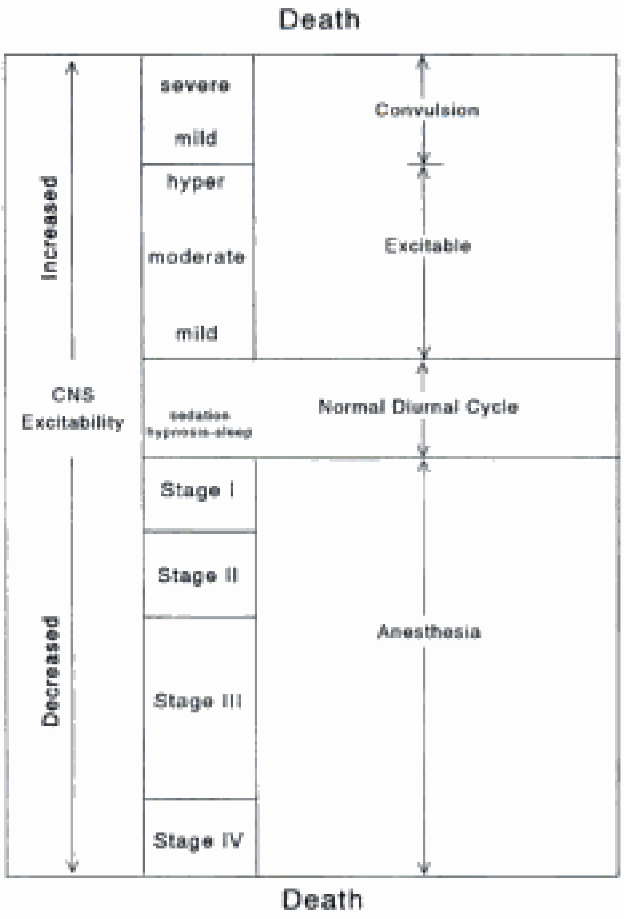

FIG. 9.7—The classic unidimensional schema of CNS excitation and depression. (Modified from Winters 1976.)

(1967) proposed replacement of the classic, unidirectional schema (Fig. 9.7) of CNS excitation and depression with a new schema that included a description of progressive states of both CNS depression and excitation (Fig. 9.8). The new schema recognized bidirectional influences of drugs acting on the CNS and was based on results of electrophysiological studies of anesthetic, excitatory, hallucinogenic, and convulsive agents in cats (Winters et al. 1967; Winters et al. 1972; Winters 1976).

Guedel's scheme also does not take into consideration the modifying influences of such things as duration of anesthesia (Dunlop et al. 1987; Steffey et al. 1987a; Steffey et al. 1987b) or varying magnitudes of surgical stimulus intensity on the signs of anesthesia (Eger et al. 1972; Steffey 1983). In modern clinical anesthetic practice it is recognized that no single observation is always reliable as a sign indicating a specific magnitude of anesthesia. Accordingly, anesthetists are encouraged to develop a basic background knowledge of both the individual to be anesthetized and the selected drugs. Current advice for anesthetic management under clinical conditions is to use an initial anesthetic loading dose just necessary to suppress purposeful movement and to observe all signs possible in each patient (Table. 9.13) and then to manipulate further anesthetic dose in relation to continual stimulus-patient response assessment. If the level of anesthesia is in doubt err on the side of an animal that is too lightly anesthetized.

Stimulus assessment is of special importance since the intensity of stimulus applied to an anesthetized animal may rapidly and markedly alter the observed signs (Eger et al. 1972; Steffey 1983). A quiet animal with reasonable vital signs may quickly show evidence of light to moderate anesthesia in the presence of intense visceral stimulation despite no change in anesthetic delivery. Common responses to anesthetic dose-stimulus interaction are given in Table 9.14.

More precise quantitative measures of anesthetic depth are of obvious interest for the clinician and essential in research. Measurement of end-expired (alveolar) concentration of inhaled anesthetics is a more precise indication of anesthetic level than clinical signs when this type of anesthetic agent is used. In addition, there is continued interest in using electrophysiological approaches to measure depth of anesthesia in both the laboratory and the operating room. For a more complete review of this focused area, see Stanski 1990.

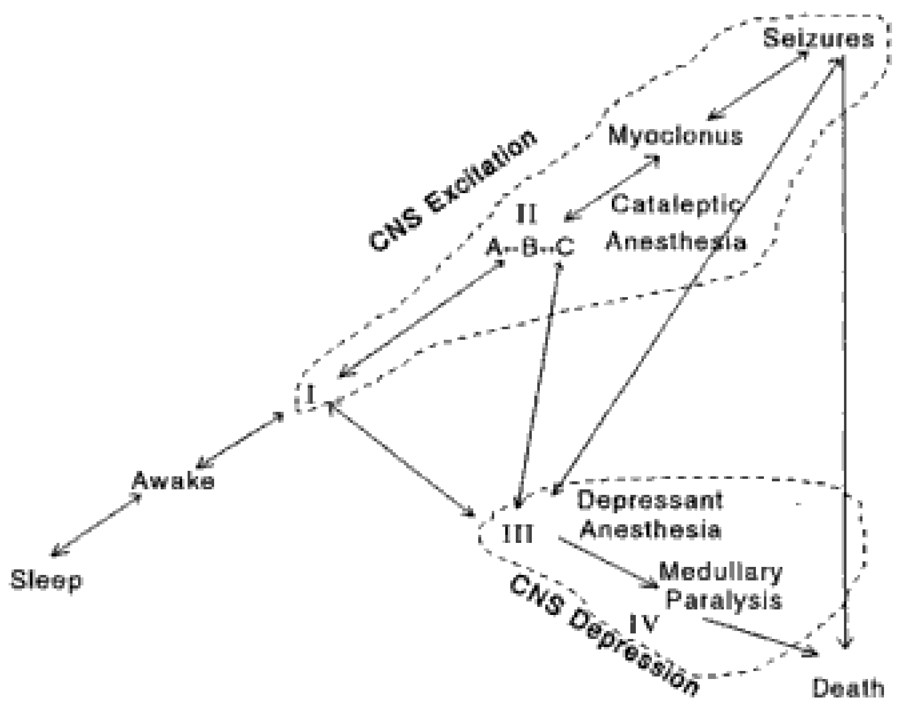

FIG. 9.8—Schematic representation of the stages of anesthesia according to Winters et al. 1972 and Winters 1976. The schematic has been modified slightly from its original description. I-IV refer to the classic stages of anesthesia.

TABLE 9.14—Common responses to anesthetic dose stimulus interaction

1. Signs of presurgical anesthesia
   a. Bradycardia, tachycardia, arrhythmia
   b. Arterial hypertension
   c. Pupillary dilation, lacrimation, globe rotation
   d. Tachypnea or breath holding
   e. Deep breathing
   f. Reduced alveolar/arterial PCO_2
   g. Limb/body movement
   h. Salivating, vomiting
   i. Swallowing
   j. Laryngeal spasm
   k. Phonating
2. Signs of deep surgical anesthesia
   a. Bradycardia, tachycardia, arrhythmia, cardiac arrest
   b. Arterial hypotension
   c. Pupillary dilation, dry cornea, centrally fixed eye
   d. Shallow breathing, respiratory arrest (*not* breath holding)
   e. Elevated alveolar/arterial PCO_2
   f. Muscle flaccidity

Nitric Oxide
- **Therapeutic Use of Inhaled NO**
- **Administration of NO**

This review of therapeutic gases centers on oxygen (O_2) and carbon dioxide (CO_2). Because of the increased interest in and effectiveness of respiratory therapy in veterinary patients and the need to administer water in the inspired breath, water vapor is also briefly discussed. Although the therapeutic value of these three gases is not uniquely associated with the central nervous system, they are discussed in this section because they have a prominent role in the management of general anesthesia. Information on nitric oxide (NO) has been briefly added to this chapter (and supplements information in Chap. 5) because it is now recognized as a major endogenous mediator of multiple physiologic processes, and as a result it offers promise as an inhaled drug for use in the clinical practice of anesthetic management and critical patient care.

PHYSICAL PRINCIPLES

Compressed Gases. Gases are normally commercially available compressed and stored in cylinders. Cylinder sizes are designated by letters, beginning at A. For medical applications, the E and H cylinder sizes are most commonly used (Table 10.1). These cylinders are normally attached directly to anesthetic or respiratory care delivery equipment, and gas inflow is regulated by calibrated gas flow meters. Users of large volumes of O_2 often have a bank of cylinders attached to a manifold supplying a hospital-wide piping system. Users of very large volumes of O_2 may also consider supply in the form of liquid O_2 (Dorsch and Dorsch 1984).

TABLE 10.1—Physical properties of gases

	Carbon dioxide	Oxygen
Chemical formula	CO_2	O_2
Molecular weight	44.01	32.00
Density (g/L at 1 atm, 15°C)	1.867	1.352
Specific gravity (air = 1 at 21°C,* 1 atm)	1.52	1.11
Boiling point (°C)	—	−183
Cylinder fillings		
Physical state in cylinder	liquid	gas
Cylinder pressure (psi at 21°C, 1 atm)	750	2200
Cylinder gas volume (L)		
Style E	1590	622
Style H	—	6900
Cylinder color code (U.S.)	gray	green

*21.1°C = 70.0°F.

Behavior of Gases. The behavior of gases in entering, leaving, and moving within the body is an important consideration in anesthesia and respiratory system therapy. Gases are composed of molecules that move about at random. The gas expands or contracts to fill the space available to it. The random movement and collision of gas molecules with the surface of the surrounding vessel exert a pressure that can be measured. The more molecules per unit volume, the greater the pressure. Temperature is important because, e.g., when a gas is heated, the activity of the molecules increases, and either the volume of the gas increases (no limit to the gas container) or the pressure of the gas increases (i.e., the volume is fixed and the number of molecular collisions therefore increases).

A mixture of gases contained within a space also imparts a pressure. In this case the total pressure of the mixture is the sum of the pressure of each gas in the mixture. That is, each gas exerts a certain fraction (F) of the total pressure. This is known as the gas's partial pressure. The usual notation for partial pressure is P_X, where the subscript X denotes the source. The unit of expression is usually mm Hg. Thus $P_{gas} = P_{total} \times F_{gas}$. The fraction is the percentage of gas in the whole/100 and is without units.

TABLE 10.2—Partial pressure (*P*) of respiratory gases during air and 100% oxygen breathing

	Inspired gas (dry)		Alveolar gas		Arterial blood	
	Air	O_2	Air	O_2	Air	O_2
PO_2 (mm Hg)	159	760	104	673	100	640
PCO_2 (mm Hg)	0.3	0	40	40	40	40
PH_2O (mm Hg)	0	0	47	47	47	47
O_2 saturation (%)	—	—	—	—	97	100
O_2 content (mL/100 mL)	—	—	—	—	019.80	22.02

Note: These values generally apply to terrestrial mammals at sea level (760 mm Hg).

Gases enter the pulmonary capillary blood from the lung alveoli (e.g., O_2) or leave the blood (e.g., CO_2) en route to the external environment via the alveoli. Blood of course acts as a medium of transport for gases and vapors between the lungs and the tissues. Gases are carried in blood simply in solution or they are reversibly combined with some constituents in the blood. Chemical combination enables more gas to be carried than would be the case with the gas simply dissolved in the liquid. The gas molecules move passively by the process of diffusion, from a place where there is a higher partial pressure of the gas to one of a lower pressure. When there is no difference in pressure of the gas molecules between the two locations, there is no net movement or transfer of molecules. The greater the difference (i.e., the steeper the partial pressure gradient), the more easily the gas exchange occurs. While the inward movement of gases from the air to alveoli is aided by mechanical means (i.e., ventilation), the passage of gas to and from tissues is solely dependent upon diffusion. In addition to the pressure gradient, the rate of gas diffusion is influenced by the distance for diffusion, the cross-sectional area of the membrane across which diffusion may occur, and the molecular weight of the gas. When gases are exposed to a gas-free liquid, an additional factor requires consideration: that of solubility. The gas molecules diffuse into the liquid until the partial pressure of the gas in the liquid equals the partial pressure in the gas phase. The number of gas molecules that enter the liquid before equilibrium is reached (i.e., equal partial pressure of the gas in the two media) is determined by the solubility of the gas. This fact is known as Henry's law (Nunn 1993). Therefore, at the same partial pressure there will be more molecules of a gas of high solubility in a liquid compared to a gas of low solubility. Henry's law applies only to gas in solution and not to a gas in chemical combination with the liquid or its constituents (e.g., O_2 with hemoglobin). Temperature also plays a role in the amount of gas dissolved in a solvent. The higher the temperature, the less the amount of gas that goes into solution.

While these principles are likely most easily understood in the context of the respiratory gases O_2 and CO_2, they also apply to absorption and elimination of other gases that pass into and out of the tissues, e.g., nitrogen and anesthetic gases. Normal values for the partial pressure of respiratory gases in terrestrial mammals breathing air at sea level (760 mm Hg) are given in Table 10.2.

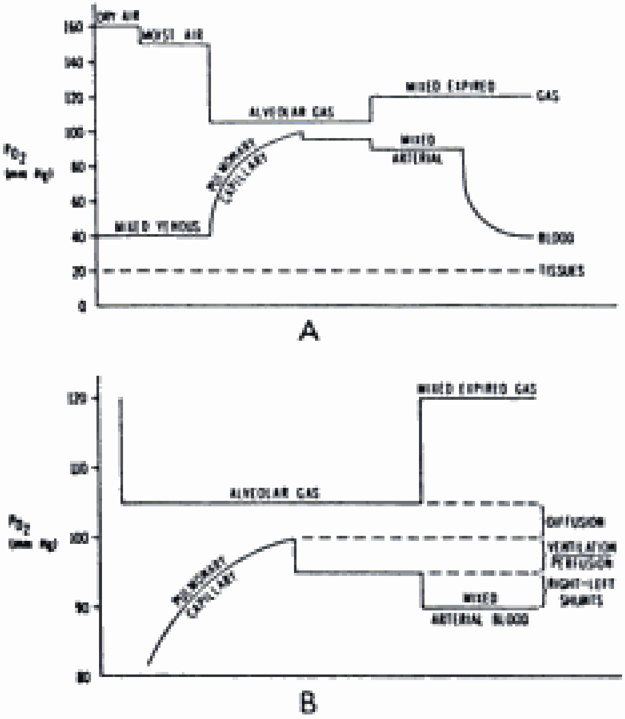

FIG. 10.1.—Oxygen tensions in blood and gas phases. Graph A shows the oxygen partial pressure (PO_2, mm Hg) in blood and gas phases of the respiratory system. Graph B shows blood and gas PO_2 within the lung and factors involved in the alveolar-arterial PO_2 difference. (From Steffey and Robinson 1983, with permission.)

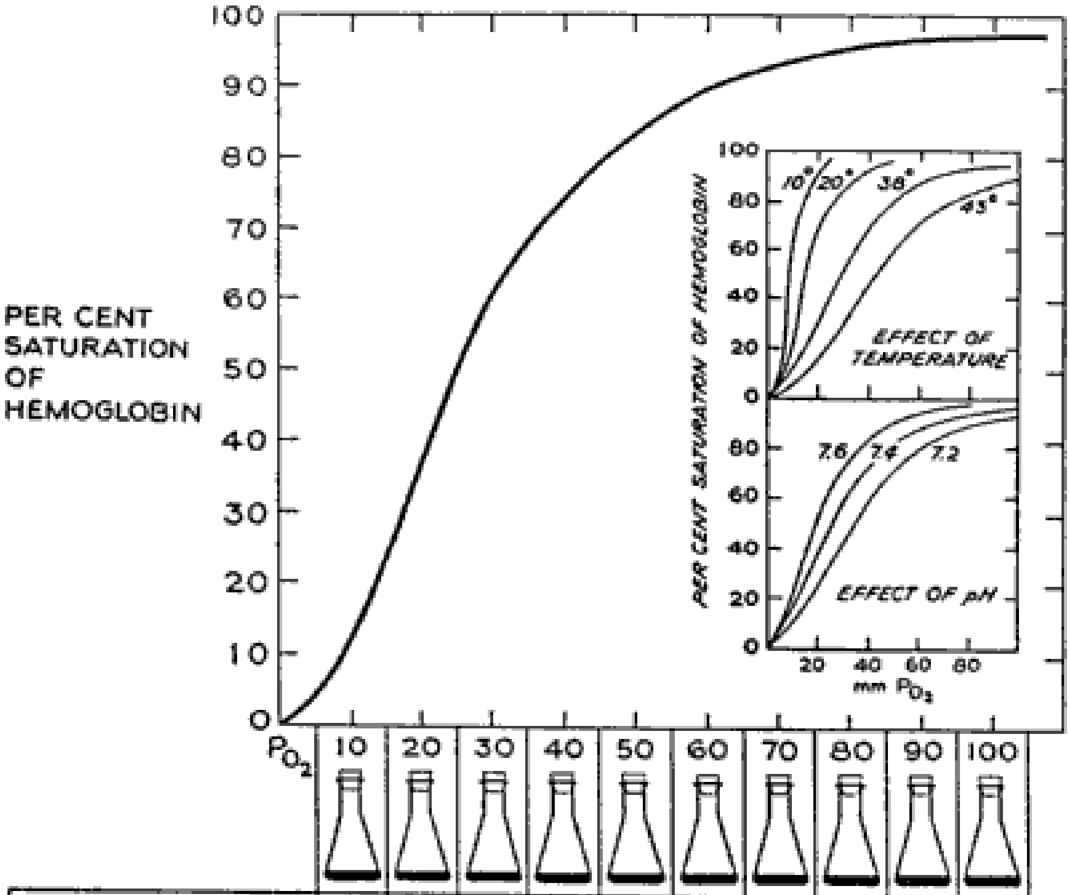
OXYGEN Most of the energy used in the mammalian body is derived from biochemical pathways that consume O_2 and are located in the mitochondria. Anaerobic pathways also exist for energy production, but they are less efficient.

About one-fifth (20.9%) of the air inhaled in each breath consists of O_2. Thus the partial pressure of O_2 (P_IO_2) of dry air at sea level is 159 mm Hg. Oxygen moves down a partial pressure gradient from ambient air through the respiratory tract. Moisture is added in the upper airway, and it mixes with alveolar gas so the PO_2 in the alveoli is reduced from 159 mm Hg (Table 10.2). Further reductions in partial pressure occur in the arterial blood, the tissue, the capillaries, and the cell, and the partial pressure ultimately reaches its lowest level within the mitochondria (Fig. 10.1). These steps in the decrease of the PO_2 are commonly referred



P_{O_2}	10	20	30	40	50	60	70	80	90	100
A WHOLE BLOOD O_2 ml O_2/100 ml BLOOD	2.73	7.06	11.49	15.12	16.85	17.98	18.75	19.14	19.57	19.80
B DISSOLVED O_2 ml O_2/100ml BLOOD	0.03	0.06	0.09	0.12	0.15	0.18	0.21	0.24	0.27	0.30
C O_2 COMBINED WITH Hb (A-B)	2.70	7.00	11.40	15.00	16.70	17.80	18.54	18.90	19.30	19.50
D % SAT. OF Hb $\frac{HbO_2}{O_2\ CAPACITY} \times 100$	13.5	35	57	75	83.5	89	92.7	94.5	96.5	97.5

FIG. 10.2.—Oxygen dissociation curves. The large graph shows a single dissociation curve for human blood when pH of the blood is 7.40 and temperature is 38°C. Effects on the curve of changes in temperature and pH are shown on the smaller graphs. The positioning of the curve is also influenced slightly according to species (not shown). (From Comroe 1965, with permission.)

to as the O_2 cascade and are more thoroughly reviewed elsewhere (Comroe 1965; Guyton and Hall 1996; Nunn 1993; Steffey and Robinson 1983; West 1992).

Oxygen is carried in the blood in two forms. About 75% is transported to the tissue in loose chemical combination with hemoglobin (Fig. 10.2). Each gram of hemoglobin can combine with about 1.34 mL of O_2. A normal value for hemoglobin concentration that broadly reflects species of importance in veterinary medicine is 15 g/dL of whole blood. Thus in the presence of normal hemoglobin concentration, arterial blood will carry about 20 mL of O_2 when the hemoglobin is fully saturated (1.34 × 15).

Hemoglobin saturation is defined as the actual O_2 content of a sample and is expressed as a percentage of the possible total carrying capacity of the sample. The saturation of hemoglobin with O_2 at different partial pressures of O_2 in blood is described by the S-shaped hemoglobin dissociation curve (Fig. 10.2).

Only about 0.03 mL of O_2 is in physical solution (dissolved in plasma) in 100 mL of blood when the PO_2 is 100 mm Hg. Although this quantity is not large, O_2 solubility has importance since it is via this pathway that O_2 passes to and from hemoglobin and the tissues. Furthermore, although the amount of O_2 carried by hemoglobin cannot increase beyond that quantity at

TABLE 10.3—Etiology of hypoxia

- I. Prepulmonary cause
  - A. Deficiency of O_2 in the inspired breath
    - 1. Low inspired O_2 concentration at normal ambient pressure (e.g., improper O_2/N_2O mixture during anesthesia)
    - 2. Normal O_2 concentration at low ambient pressure (e.g., high altitude)
  - B. Reduced ventilation
    - 1. Anatomic obstruction to gas flow (e.g., airway obstruction)
    - 2. Mechanical deficit (e.g., neuromuscular block)
    - 3. System control deficit (e.g., drug- or disease-induced CNS depression)
- II. Pulmonary cause
  - A. Impaired diffusion at alveolar-capillary membrane (e.g., pulmonary edema)
  - B. Increased right to left (i.e., venous to arterial) pulmonary vascular shunt (e.g., congenital cardiac disease)
  - C. Mismatching of ventilation to perfusion
- III. Postpulmonary cause
  - A. Inadequate circulatory system transport of O_2
    - 1. Reduced hemoglobin concentration (e.g., anemia)
    - 2. General dicrulatory deficiency (e.g., decreased cardiac output)
    - 3. Localized circulatory deficiency (e.g., decreased regional blood flow)
  - B. Inadequate tissue oxygenation
    - 1. Inadequate unloading of O_2 from hemoglobin (e.g., defiency in 2, 3-DPG)
    - 2. Tissue diffusion impairment (e.g., edema)
    - 3. Abnormally high tissue O_2 demand (e.g., local hyperthermia)
    - 4. Cellular enzyme system malformation (e.g., cyanide poisoning)

which hemoglobin is fully saturated, the total amount in solution increases directly with an increase in P_aO_2.

The O_2 content of blood is the sum of the volume of O_2 carried in solution and that transported via hemoglobin per unit volume of blood (again by convention, 1 unit volume is usually considered 100 mL). Changes in the amount of hemoglobin per 100 mL of blood will alter O_2 content but not the percent saturation of hemoglobin or P_aO_2.

A number of factors influence the amount of O_2 transported by hemoglobin and so shift the oxygen-hemoglobin dissociation curve to the left or to the right. Acidosis, increased body temperature, and increased concentrations of 2,3-diphosphoglycerate (2,3-DPG, a product of erythrocyte metabolism) all shift the curve to the right (i.e., decrease the affinity of hemoglobin for O_2 and facilitate unloading of O_2); and increased blood pH, decreased body temperature, and decreased concentration of 2,3-DPG all have an opposite effect (Fig. 10.2).

When the O_2 content of arterial blood is very low, unpigmented mucous membrane color may change from pink to blue. This is known as cyanosis and is due to the darker color of deoxyhemoglobin. Cyanosis appears when about 5 g/dL of deoxyhemoglobin are present in arterial blood.

Oxygen Lack. The lack of O_2 represents a serious threat to the vitality of the organism and is variously described. *Hypoxia* is a general term that signifies a decrease in O_2 below normal levels in inspired gas, alveolar air, blood, or tissues (Comroe 1965). In recent times it has been most commonly used to designate insufficient oxygenation of tissues. *Hypoxemia* signifies a decrease in arterial hemoglobin O_2 saturation below normal or a below-normal P_aO_2 or both.

The causes of hypoxia can be conveniently classified according to prepulmonary, pulmonary, and postpulmonary sites (Table 10.3). Hypoxemia is not surprisingly associated with prepulmonary and pulmonary etiologies. Indeed, multiple etiologies frequently occur simultaneously under clinical conditions.

Physiological responses to hypoxia may be considered direct or indirect. The direct responses relate largely to the cardiovascular and respiratory systems, and the indirect effects are those secondary effects due to hypoxia-associated failure of vital organs such as the heart, brain, kidney, and liver. When O_2 delivery to the tissues falls below a critical level, vigorous compensatory mechanisms come into play to attempt to minimize harm to the individual.

The direct responses are usually robust and tend to over ride conflicting mechanisms. Some compensatory mechanisms may be impaired by concurrent drug therapy (e.g., anesthetics) or vary in extent depending on species (Comroe 1965; Guyton and Hall 1996; Nunn 1993).

Cardiac output and regional blood flow to vital organs increase largely as a result of an increase in heart rate and a decrease in peripheral vascular resistance. Tachypnea and hyperventilation are the prominent respiratory system responses due to stimulation of the peripheral chemoreceptors. Pulmonary arterioles constrict, and pulmonary artery blood pressure increases, presumably in an attempt to better balance pulmonary blood flow with regional lung ventilation.

Lack of O_2 impairs tissue function and if prolonged causes cellular death and necrosis. Cellular survival times depend on many factors but are largely influenced by inherent tissue characteristics of O_2 consumption and local O_2 stores. Survival conditions can be improved by, e.g., decreasing cellular metabolism (e.g., hypothermia). Hyperbaric oxygenation improves O_2 stores.

The cerebral cortex is especially vulnerable to hypoxia, and change in cerebral function is a very sensitive indication of O_2 lack. In humans, a change in mood is an early sign of hypoxia, and with continued insult or an increased magnitude of hypoxic conditions, mental performance gradually deteriorates and consciousness may ultimately be lost. In anesthetized animals anesthetic requirement is decreased (Cullen and Eger 1974). Skeletal muscle, on the other hand, is much less sensitive to an insult of similar magnitude. Heart and hepatic cells are intermediary in their vulnerability to hypoxic conditions, and hepatic centrilobular necrosis is a consequence of some mishaps.

OXYGEN-DERIVED FREE RADICALS AND CELL INJURY. Organ survival after a period of hypoxia depends also on factors that influence O_2 transport during the recovery phase. Restored tissue perfusion and oxygenation before hypoxic cell death can sometimes paradoxically result in an accelerated form of cell injury (ischemia-reperfusion injury). Events associated with reperfusion following ischemia produce further tissue injury via the generation of O_2 free radicals. The resulting injury is distinct from that occurring as a result of the preceding ischemic period.

A free radical is a molecule containing an odd number of electrons. This state is chemically very reactive. Of the radicals formed in biological systems, most attention is focused on superoxide, a species formed when O_2 is reduced by a single electron (Bhagavan 1992; McCord 1985, 1987; Pryor 1986). Superoxide anion is also produced by O_2-reducing enzymes of phagocytes (neutrophils, mononuclear phagocytes), which defend the host against invading organisms. Current thinking regarding the etiology of ischemia-reperfusion injury is that the initial hypoxic stress results in the production of hypoxanthine and O_2-radical-producing xanthine oxidase. During reperfusion, molecular O_2 is reintroduced into the tissues, where it supports the burst production of more superoxide anion and hydrogen peroxide, which in turn yields highly reactive cytotoxic components. Granulocytes are attracted to this area, are activated, and adhere to microvascular endothelium. These granulocytes then in turn cause further endothelial cell damage via release of superoxide and various proteases (Granger 1988; McCord 1987; Welbourn et al. 1991).

Dysfunction induced by free radicals is likely a major component of ischemic diseases of the heart, bowel, liver, kidney, brain, and skeletal muscle (McCord 1985; Granger et al. 1981; Perry and Fantini 1987; Karmazyn 1991). In addition, reperfusion of ischemic tissue may lead to an inflammatory reaction that is not just confined to the region of injury (Welbourn et al. 1991; McCord 1987).

Reperfused tissues are protected in a variety of laboratory models by scavengers of superoxide radicals (superoxide dismutase) and hydroxyl radicals (dimethyl sulfoxide) or by inhibitors of xanthine oxidase (allopurinol) (Welbourn et al. 1991; McCord 1985).

CHRONIC OXYGEN LACK. A gradual decline in O_2 tension occurs as the vertical distance from sea level increases. The decrease in PO_2 is a direct result of the decrease in barometric pressure with increasing altitude since O_2 concentration in the earth's atmosphere remains at slightly less than 21% of the total barometric pressure. For example, the PO_2 of ambient air at sea level is 159 mm Hg (0.21 × 760 mm Hg; Table 10.2) but 110 mm Hg (0.21 × 523 mm Hg) at 10,000 feet and only 47 mm Hg (0.21 × 226 mm Hg) at 30,000 feet.

Adaptations to high altitude and the associated lowered inspired PO_2 depends to a certain degree on whether the individual has resided at high altitude since birth or has only recently (within weeks) traveled there. However, in general, the adaptation process includes an increase in alveolar ventilation, hemoglobin and 2,3-DPG production, respiratory gas-diffusing capacity in the lungs, and vascularity of tissues. There is also an improved ability of the cells to use a more limited PO_2. Occasionally, adjustments fail to occur in individuals, and their health and well-being are affected (Guyton and Hall 1996; Nunn 1993; West 1992).

Oxygen Excess. *Hyperoxia* refers to an increase in P_aO_2 above normal for animals breathing air at sea level and can be produced in two ways. First, an elevation in P_aO_2 at sea level can result from increasing the inspired O_2 fraction (concentration). Common clinical examples of O_2 enrichment of the inspired breath include the practice of using O_2 as an anesthetic carrier gas or to supplement the inspired breath of a critically ill, hypoxemic patient. Alternatively, hyperoxia may be produced by elevation of the ambient pressure with or without a change in the oxygen concentration, i.e., hyperbaric oxygenation.

Hyperoxia can be detrimental in a number of ways, including depression or cessation of ventilation (apnea), retrolental fibroplasia, fire, and O_2 toxicity. Retrolental fibroplasia is a condition that frequently develops in prematurely born infants who in the treatment of prematurity are exposed to high concentrations of O_2 (Ashton 1979; Patz 1965). The condition may cause permanent blindness as a result of O_2-associated retinal damage. The crucial determinant appears to be the magnitude of P_aO_2. The incidence of this problem has been reduced via monitoring P_aO_2 and controlling the inspired O_2 concentration to facilitate a P_aO_2 of 60–70 mm Hg in the infant.

All tissues of the body can be directly injured by sufficiently high PO_2 but because the lung is exposed to the highest partial pressure, it is very vulnerable. Normobaric O_2 toxicity of the lung is related to the magnitude of inspired O_2 concentration and the duration of exposure. Except for tracheitis, which develops early in the exposure, normal humans can likely tolerate an elevated inspired O_2 concentration at sea level for at least 24 hours without any serious lung tissue injury. Longer exposure times and/or underlying disease or other physiological factors that reduce the subjects' tolerance (e.g., age, nutrition status, previous exposure to O_2 or other oxidants) will result in parenchymal injury.

Hyperbaric O_2 accelerates the effects of O_2 toxicity and rapidly induces convulsions, suggesting the cells of the central nervous system are also very sensitive to hyperoxia (Deneke and Fanburg 1982).

The pathology of O_2 toxicity based on studies of animals and human beings is nonspecific and includes atelectasis, pulmonary edema, inflammation, and alveolar membrane thickening. The endothelial cells of the lung seem to be affected earliest, resulting in altered cell permeability and ultimately noncardiogenic edema. Damage to the alveolar type 1 epithelial cells contributes to loss of alveolar stability and later local fibrosis. Although the pathogenesis of hyperoxic O_2 toxicity is not fully established, the formation of excess O_2 free radicals and associated cytotoxic species is currently viewed as the probable mechanism. Thus xanthine oxidase and neutrophil-induced O_2-metabolite-mediated injury seem to participate in both pulmonary O_2 toxicity and ischemia-reperfusion injury. Readers will find reviews by Deneke and Fanburg (1982), Crapo et al. (1983), Repine and Tate (1983), Jackson (1985), and Nunn (1987) helpful for further information on this subject.

Therapeutic Uses of Oxygen. There are two primary clinical uses of O_2 in veterinary patients: correction of hypoxemia and hypoxia and as a diluent or carrier gas for inhalation anesthetics. The absolute O_2 concentration used as therapy for hypoxemia varies with clinical circumstances and the physical status of the patient. Because of its potential for harm, especially with prolonged respiratory care and O_2 use, the inspired O_2 concentration used for treatment of hypoxemia needs to be closely monitored and controlled. Usually an inspired O_2 concentration less than 50% is desirable if prolonged (12 hours or more) administration is anticipated. The adequacy of oxygenation is monitored via serial determination of sampling of arterial blood and measurement of P_aO_2. On the other hand, because of the relatively short duration of exposure and the added complexities of multiple gas delivery, an inspired O_2 concentration greater than 90% is the common, if not usual, circumstance associated with the management of inhalation anesthesia of veterinary patients.

A third clinical use of supplemental O_2 administration is to facilitate the absorption of inert gas(es) from gas pockets within the body. Gas spaces exist in the body under usual and sometimes under abnormal circumstances. Sites within the body include the gastrointestinal tract, peritoneal and pleural cavities, alveoli whose gas entrance/exit paths are not in free communication with airways, and subcutaneous locations. The gas contained within these pockets (largely nitrogen) will be absorbed into the blood and lost from the body more rapidly if O_2 is inhaled because of the individual gas partial pressure differences between the gas space and the blood.

Finally, O_2 can be administered at more than one atmosphere (hyperbaric conditions) if the patient is placed in a rigid container. The clinical application of hyperbaric O_2 delivery to veterinary patients is a rare event. Its use with animals is more commonly associated with investigative activities. It has application to human patients with specific clinical conditions such as gas gangrene caused by clostridial organisms, decompression sickness, or air embolism (the therapeutic goal is for an increased hydrostatic pressure and the establishment of a gradient for outward diffusion of inert gas) or those patients who require a P_aO_2 in excess of that at normobaric circumstances (e.g., P_aO_2 in these patients is normal but blood flow to a region is reduced) (Eckenhoff and Longnecker 1990; Guyton and Hall 1996; Nunn 1993).

Administration of Oxygen. Oxygen is usually administered by inhalation using a variety of available equipment (Dorsch and Dorsch 1984; Shapiro et al. 1975; Short 1987; Hall and Clarke 1991; Haskins 1986). An exception occurs in circumstances in which extracorporeal blood circulation is used (e.g., open heart surgery), in which case O_2 is made to come in direct contact with blood. Terminal devices used to supplement O_2 in the inspired breath of awake or lightly sedated/depressed animals include masks, nasal cannulas, and specially designed gas delivery cages. To facilitate maintenance of the airway during O_2 delivery in anesthetized or markedly depressed critically ill patients, endotracheal intubation is used. The endotracheal tube provides direct access to the airway and seals off the walls of the airway to minimize any possibility of lung aspiration of foreign material. The tube also allows better control of inspired gases and facilitates use of mechanical ventilation in patients with compromised ventilatory function (Short 1987; Hall and Clarke 1991; Haskins 1986).

CARBON DIOXIDE. Carbon dioxide (CO_2) is present in the atmosphere in minute proportions (0.03%). It is stored in cylinders and available commercially for medical use. Carbon dioxide is a waste product of tissue metabolism and is carried in blood primarily in three forms: physical solution, combined with proteins as carbamino-compounds in the red blood cell (about 85% of the total) and plasma, and as bicarbonate in plasma (CO_2 readily combines with water to form carbonic acid, which then dissociates to bicarbonate and hydrogen ions). The CO_2 dissociation curve relates P_aCO_2 to the CO_2 content of blood. Unlike the oxyhemoglobin dissociation curve, this curve has no plateau, so that as P_aCO_2 increases, blood CO_2 also increases (Comroe 1965; Guyton and Hall 1996; Nunn 1993). The CO_2 produced in the body is lost primarily via the lungs. The alveolar PCO_2 is inversely related to the magnitude of alveolar ventilation. Since there is virtually no diffusion impediment to pulmonary capillary-alveolar diffusion of CO_2, P_aCO_2 mirrors the P_ACO_2. Thus P_aCO_2 and alveolar ventilation are also inversely related.

The normal range for the P_aCO_2 in terrestrial mammals is 35–45 mm Hg. Each species usually exhibits a narrower range within this broader range. Clinically, hypoventilation is present when P_aCO_2 exceeds normal (i.e., hypercapnia), and hyperventilation is indicated by a lower than normal P_aCO_2 (i.e., hypocapnia). When alveolar ventilation is decreased (or CO_2 is inhaled), the P_aCO_2 increases and blood pH decreases. This change in pH_a is referred to as respiratory acidosis. Conversely, when alveolar hyperventilation occurs (e.g., overzealous mechanical ventilation), P_aCO_2 decreases and pH_a increases, resulting in respiratory alkalosis. Since CO_2 is freely diffusible, rapid intracellular pH changes also occur.

Changes in the magnitude of P_aCO_2 have important pharmacological effects. However, as pointed out by Nunn (1987), a number of issues relevant to our understanding of the etiology of these effects must be appreciated. First, species differences, especially in the magnitude of response to alterations in P_aCO_2, sometimes make interpretation of findings in the target species difficult. Second, the pharmacological effects of CO_2 may occur because of its direct effect on tissues or via its ability to alter intracellular and extracellular pH. Finally, because of its universal nature and ability to rapidly equilibrate throughout the body, its effects are rapidly produced at different sites so that there may be additive, synergistic, or antagonistic influences on a resultant effect. For example, a direct effect of CO_2 is to depress muscle function, which in the heart results in a decreased myocardial contractility. This in turn will cause a decreased cardiac output. At the same time it causes an endogenous release of catecholamines, which in turn results in an overriding increase in cardiac output in the healthy, sympathetically intact subject. The influence of changes in P_aCO_2 will be briefly reviewed below keeping in mind these difficulties. Also, since the effects of hypocapnia are less well defined than those of hypercapnia, discussion emphasis will be on effects of increased P_aCO_2. The review will emphasize effects related to general anesthesia and the unconscious, critically ill patient.

Hypercapnia. Hypercapnia has important effects on the cardiovascular system, the central and autonomic nervous systems, and the respiratory system. General influences on other organs (e.g., kidneys) are largely related to more direct effects on control of organ function via the nervous system or blood flow.

CARDIOVASCULAR SYSTEM. The observed response represents a balance between the direct effect of CO_2 on the target tissues and excitatory effects mediated via the nervous system (Cullen and Eger 1974; Guyton and Hall 1996; Nunn 1993).

Carbon dioxide causes a direct depression of myocardial contractility (as determined from isolated heart muscle preparations) as well as a depressant effect on myogenic activity in the blood vessels. Consequently, direct unopposed actions of CO_2 foster a decrease in cardiac output and a reduction in peripheral vascular resistance.

In the subject with intact autonomic control of cardiovascular function, the direct effect of CO_2 is overcome by the stimulant effect of the sympathetic nervous system. Consequently, with hypercapnia cardiac output is increased (increased stroke volume), and if there is a change in arterial blood pressure, an increase is the predominant change (Cullen and Eger 1974; Cullen et al. 1990). At superhigh levels of P_aCO_2, cardiac output may decrease (Nunn 1993).

The incidence of cardiac arrhythmias increases with an elevation in P_aCO_2. The impact of this change is related to other factors (e.g., anesthetic agent, anesthetic dose, species, and the animal's physical status).

Regional blood flow is also heavily influenced by an increase in P_aCO_2. For example, cerebral vessels are dilated by hypercapnia. The loss of autoregulation and the increase in cardiac output accompanying hypercapnia result in an increase in intracranial (an enclosed space) pressure, which may be further influenced by some anesthetic agents and techniques (Cullen et al. 1990). These actions are usually not good for the patient's well-being, especially in the presence of any underlying cerebral pathology.

CENTRAL NERVOUS SYSTEM. Three basic consequences of an increase in P_aCO_2 on the central nervous system are relevant to this discussion: (1) effects on cerebral blood vessels and the secondary effects on cerebrospinal fluid and intracranial pressure, (2) the effect on breathing, and (3) the effect on general neuronal activity (Nunn 1993).

Intracranial pressure tends to increase with hypercapnia largely as a result of cerebral vascular vasodilation, as discussed above.

In spontaneously breathing individuals, the addition of CO_2 to the inspired breath causes an increase in P_aCO_2 that in turn causes ventilation to increase. The CO_2 acts primarily by changing the H^+ concentration at the central chemoreceptor area which is located close to the ventrolateral surface of the medulla (Guyton and Hall 1996; Nunn 1993; West 1992). Concurrent hypoxia adds to the response to hypercapnia via peripheral chemoreceptor stimulation, and anesthetics depress the response, usually in a dose-dependent manner (Nunn 1993; Weiskopf et al. 1974; Hickey et al. 1971).

Hypercapnia depresses general neuronal function and if sufficiently high causes general anesthesia (Clowes et al. 1955; Eisele et al. 1967; Klemm 1964; Mattsson et al. 1972). In dogs a P_aCO_2 above 95 mm Hg has been shown to be progressively narcotic and reduces the amount of concurrently administered halothane required to maintain a constant depth of anesthesia. Anesthesia was achieved with CO_2 alone at a P_aCO_2 above 245 mm Hg (Eisele et al. 1967). It is advocated as a sedative for small laboratory animals prior to euthanasia (Urbanski and Kelley 1991; Blackshaw et al. 1988; Danneman et al. 1997). Use of CO_2 as an anesthetic for minor surgery in human beings has also been reported (Leake and Waters 1928). At concentrations below those causing general anesthesia, CO_2 may cause sedation or convulsions in some otherwise-unmedicated individuals. Indeed, review of available literature suggests that especially in susceptible individuals like human beings there is a progressive depression of central nervous system activity as the P_aCO_2 is increased up to about 150 mm Hg; above this a stage of central nervous system excitation and convulsions occurs. With a continued increase in P_aCO_2 (beyond 35%, inspired) this second stage is followed by progressive depression of cerebral electrical activity and general anesthesia (Clowes et al. 1955).

AUTONOMIC NERVOUS AND ENDOCRINE SYSTEMS. Increased sympathetic adrenergic activity is widely recognized as the cause for many of the actions or modification of actions of hypercapnia. Effects originate both centrally and peripherally (Nunn 1993). Hypercapnia results in an increase in plasma concentrations of both epinephrine and norepinephrine (Millar 1960).

EFFECTS OF CO_2 ON OXYGENATION. A major consequence of hypercapnia is a decrease in alveolar O_2 concentration. The O_2 reduction is of particular concern if the inspired gas mixture also includes nitrogen and/or nitrous oxide. Additional CO_2 molecules occupy space in the lung previously available for O_2. This situation thereby reduces the alveolar PO_2, and hypoxemia may result.

Hypercapnia can ultimately influence arterial and tissue oxygenation in other ways. For example, hypercapnia can induce improvements in ventilation and cardiac output in spontaneously breathing animals. An increase in P_aCO_2 also causes hemoglobin to have a reduced affinity for O_2. Both of these effects oppose the alveolar-O_2-diluting effect and maintain or enhance O_2 delivery. However, further discussion on this is beyond the scope of this review; interested readers are referred to appropriate sections in textbooks of respiratory physiology for additional information (Comroe 1965; Guyton and Hall 1996; Nunn 1993).

EFFECTS ON DRUG ACTIONS. Hypercapnia may affect concurrently administered drugs a number of ways. Altered regional blood flow caused by an increase in P_aCO_2 may change drug distribution. In addition, an increase in P_aCO_2 decreases blood pH (respiratory acidosis), thereby influencing the degree of ionization of drugs. Either or both of these consequences may be substantial enough to alter the drug's pharmacokinetic characteristics to a point of investigative or clinical concern.

CLINICAL USE OF CO_2. The main therapeutic indication for the administration of CO_2 is to stimulate ventilation. There is evidence to show that at least mild hypercapnia improves cardiac output and arterial blood pressure, especially in anesthetized patients. Carbon dioxide is used to rapidly render unconscious and euthanize small laboratory animals.

Hypocapnia. As previously noted, pharmacological effects of hypocapnia are less well defined than those of hypercapnia. The effects manifested during conditions of lower than normal P_aCO_2 are also dependent on whether conditions relate to active pulmonary hyperventilation as might occur in states of anxiety or in spontaneously breathing patients in light planes of anesthesia or alternatively in anesthetized or critically ill patients whose ventilation is mechanically controlled to cause hypocapnia. The presence or absence of mechanical effects of altered intrathoracic pressure swings on blood circulation modifies any pharmacological effects of CO_2 or accompanying pH changes.

In the anesthetized subject the prominent effects of hypocapnia include a general reduction in cardiovascular performance (e.g., decrease in cardiac output and arterial blood pressure) that may be considerable in magnitude. For example, cerebral blood flow is decreased as P_aCO_2 is decreased from 40 to 20 mm Hg. Hypocapnia also causes decreased activity of respiratory control centers and an accompanying decrease in alveolar ventilation.

There is a clinical impression that lowering P_aCO_2 during the anesthetic management of patients contributes to the anesthetic effect (Geddes and Gray 1959). However, studies of dogs (Cullen and Eger 1971; Eger et al. 1965) and humans (Bridges and Eger 1966) could not demonstrate a reduction in halothane anesthetic requirement.

CLINICAL USES. Decreasing P_aCO_2 via hyperventilation during anesthesia is a common tactic to facilitate controlled mechanical ventilation in the absence of neuromuscular blockade or excessive anesthetic depth. It is also used to attempt to minimize or prevent neurological complications that might arise from increased intracranial pressure in patients with central nervous system pathology and/or to shrink brain size (via reduced blood flow) and facilitate surgery within the cranial cavity.

WATER VAPOR. Humidity is water in its vapor state: invisible moisture. It is not technically a gas, because the critical temperature of water has not been reached (Scanlan et al. 1990). When air is inspired, it is normally warmed and humidified to saturation at body temperature. This process is largely complete by the time the gas reaches the larynx. In clinical circumstances in which the nasal cavity, mouth, and pharynx are bypassed, as with tracheostomy or endotracheal intubation, the process of hydrating inspired air is accomplished less efficiently by the mucosa and the mucous blanket of the trachea and more distal airways. Normal individuals can withstand this shift in site of air hydration without apparent clinical consequence, but patients with airway injury often cannot.

Humidity can be described in a number of ways. For example, the absolute humidity is the actual water content of a gas and is recorded in terms of weight per

TABLE 10.4—Water vapor pressures and content (saturated) at selected temperatures

Temperature	Vapor pressure	Water vapor content*
(°C)	*(mm Hg)*	*(mg/L)*
20	17.5	17.3
21	18.7	18.4
22	19.8	19.4
23	21.1	20.6
24	22.4	21.8
25	23.8	23.1
26	25.2	24.4
27	26.7	25.8
28	28.3	27.2
29	30.0	28.8
30	31.8	30.4
31	33.7	32.1
32	35.7	33.8
33	37.7	35.6
34	39.9	37.6
35	42.2	40.0
36	44.6	41.7
37	47.1	43.9
38	49.7	46.2

*Absolute humidity.

volume, e.g., mg/L (Table 10.4). Relative humidity is the relationship of the actual water vapor content of a gas and its capacity to carry water at a given temperature and is expressed as a percentage (of that capacity). Capacity increases with an increase in temperature.

Water as a vapor acts like a gas. The molecules of a liquid, like those of a gas, are in constant motion. Some of the molecules at the air-liquid interface escape from the liquid and enter the gaseous space above. At equilibrium the number of molecules leaving the surface of the liquid equals the number returning from the gas space above. The greater the temperature, the greater the liquid molecules' kinetic energy and therefore their tendency to leave and enter the gas phase. Water molecules in the vapor state exert a pressure, and as the temperature increases, the partial pressure of water vapor also increases. Therefore, we can describe water vapor in terms of its vapor pressure: the pressure (commonly in mm Hg) that water can exert at a given temperature. This is true regardless of the ambient pressure. When the atmosphere is completely saturated with water vapor at a given temperature, the relative humidity is 100%. This temperature-pressure relationship is well known (Table 10.4) and is an important concept in our therapeutic application of respiratory and anesthetic vapors. For example, as noted in Table 10.4, the vapor pressure of water at a body temperature of 38° C (100.4° F) is 50 mm Hg. We know that as air is inhaled, it is humidified to saturation. Recall that the total pressure exerted by the atmosphere is the sum of the pressures exerted by its component gases (i.e., the partial pressure of each of the component gases of the gas mixture; Dalton's law) (Scanlan et al. 1990; Comroe 1965; West 1992). The water vapor added to inspired gas (remember this is temperature dependent) thus reduces the partial pressure of O_2 in the inspired gas. That is, the PO_2 of moist inspired gas in the trachea of an animal with a body temperature of 38° C is 20.9% of 760 − 50 mm Hg (149 mm Hg), not 20.9% of 760 (159 mm Hg) as in dry air (the atmospheric or total gas pressure at sea level is taken as 760 mm Hg). This can be stated in general form as partial pressure of humidified sample = fractional concentration of dry gas × (barometric pressure − saturated vapor pressure).

Therapeutic Uses of Water Vapor. The humidification of inspired air normally helps maintain the hydration of the mucous blanket of the airways. A decrease or loss of this action promotes crusting of the respiratory mucosa, thick airway secretions, and reduced efficiency of mucociliary transport. Some clinical examples in which administration of water vapor is indicated include a patient whose upper airways are bypassed for a prolonged period via tracheostomy or oro-endotracheal intubation. Another may be the long-term delivery of inspired gases derived in part or totally from cylinders. The gas delivered from these sources is dry and can have a rapid drying effect on respiratory system mucosa.

Administration of Water Vapor. Water vapor may be delivered as a vapor (humidity) or as a suspension of very fine particles of liquid (water droplets) in a gas (aerosol) (Scanlan et al. 1990; Shapiro et al. 1975; Haskins 1986). Water may also be directly instilled into the tracheobronchial tree. Water can be given alone or with various medically active constituents, including electrolytes (e.g., saline). Humidifiers can deliver water vapor at room temperature to make the gas more comfortable to breathe or at body temperature to increase the amount of water that is delivered in a breath (Table 10.4). Water volume over that limited by temperature can be accomplished with aerosol generators. In addition, particle size of aerosols can be varied and determines the site of water deposition within the respiratory tract. Therefore, if the clinician knows the preferred level of aerosol deposition in the airway, the device best suited for the therapeutic effect can be selected.

Likely the greatest problem related to this mode of therapy is infecting a patient via contaminated respiratory therapy equipment. Other potential problems include thermal injury to the respiratory mucosa, fluid overload via water absorption, and airway obstruction, especially in very young or small patients.

NITRIC OXIDE. In 1987 Palmer et al. and Ignarro et al. (1987) separately proposed that the biological actions of endothelium-derived relaxing factor (Furchgott and Zawadski 1980) are due to the endogenous release of nitric oxide (NO). Nitric oxide is formed from the amino acid L-arginine by a family of enzymes, the NO synthases, and is recognized as a major endogenous mediator of a variety of diverse physiological processes (see Chap. 2), including smooth muscle relaxation, platelet inhibition, central and autonomic neurotransmission, tumor cell lysis, bacteria killing, and stimulation of hormonal release. Its formation in vascular endothelial cells in response to chemical and physical stimuli helps to maintain a vasodilator tone that is essential for regulation of local blood flow and pressure (Moncada et al. 1989; Vanhoutte 1989; Furchgott 1990). Following its formation in the endothelium, NO diffuses into adjacent vascular smooth muscle and activates soluble guanylate cyclase; the subsequent increased synthesis of the second-messenger cyclic guanylate 3′,5′-monophosphate produces smooth muscle relaxation and vessel dilation (Ignarro 1989).

Therapeutic Use of Inhaled NO. Nitric oxide is not effective when administered directly into the bloodstream because it is extremely rapidly inactivated (in 3–5 seconds) by hemoglobin (Gibson and Roughton 1957).

The potential beneficial role of nitro-compounds in problems of the lung has been appreciated for many years. In the past five years there has been an explosion of knowledge related to the therapeutic applications of NO in the lung. It is now widely appreciated that alterations of NO metabolism or the therapeutic and diagnostic use of NO or its derivatives may play an important role in pulmonary hypertension (including hypoxic pulmonary vasoconstriction, or HPV) and some other reversible lung diseases. With pulmonary hypertension the vasodilatory action specific to the pulmonary versus the systemic vasculature is of critical importance.

Frostell et al. (1991) reported that inhalation of 5–80 ppm NO caused pulmonary vasodilation during pulmonary vasoconstriction (e.g., caused by severe hypoxia; HPV). Exogenous inhaled NO diffuses from the alveoli to the pulmonary vascular smooth muscle and produces pulmonary vasodilation. The action is selective since any NO that diffuses into the blood is rapidly inactivated before it can produce any systemic effects (Frostell et al. 1993). In addition, inhaled NO is known to cause bronchodilation in the guinea pig (Dupuy et al. 1991). Thus, as a result, the use of inhaled NO is being widely and intensely investigated as a therapeutic possibility in pulmonary medicine.

Although published reports of its use in clinical practice (e.g., Frostell et al. 1993; Rossaint et al. 1993; Wysocki et al. 1994) are increasing in number, its use is still considered experimental. The many unresolved issues include the potential pulmonary toxicity of inhaled NO. Toxicity may be due to either NO itself or its reactive metabolite NO_2 (nitrogen dioxide) (Stavert and Lehnert 1990; Hugod 1979); both have been the subject of study for many years (Morrow 1984). Nitric oxide is a common air pollutant, and acute lung injury can occur at levels over 50–100 ppm. In addition, NO binds to hemoglobin to form nitrosylhemoglobin, which is rapidly converted to methemoglobin (Gibson and Roughton 1957).

In the presence of O_2, NO is converted to NO_2. The rate of NO_2 production in simulated and actual clinical conditions has been reported (Foubert et al. 1992; Bouchet et al. 1993; Lindberg and Rydgren 1998). Nitrogen dioxide has long been recognized as responsible for Silo Fillers Disease (a syndrome of pulmonary edema, hemorrhage, and bronchiolitis; NO_2 is a product of grain fermentation) and other related lung injury syndromes (Williams et al. 1971). Occupational safety and health guidelines recommend 5 ppm as the upper limit of exposure to NO_2 (Centers for Disease Control 1988), and recent guidelines for NO_2 exposure during therapeutic use of inhaled NO recommend less than 1 ppm (Zapol et al. 1994).

Administration of NO. Nitric oxide is a gas at room temperature (and down to −152° C) and is usually supplied in a cylinder as an inert mixture with nitrogen ($NO\text{-}N_2$). These preparations may, if not carefully prepared, contain higher oxides of nitrogen, including NO_2. Nitric oxide has a density relative to air of 1.227 and a water/gas solubility of 4.6 (20° C).

Guidelines for appropriate administration of NO have been published (Tibballs et al. 1993; Zapol et al. 1994; Nishimura et al. 1995; Lindberg et al. 1997; Body et al. 1995). The mode of delivery of inhaled NO must allow for precise, rapid control of NO concentration. Waste and excess gases should be scavenged to reduce potential dangers associated with occupational exposure to NO or NO_2.

Both NO and NO_2 concentrations in the inspired limb of the breathing circuit and in the immediate environment should be continuously monitored by chemiluminescence or electrochemical analyzers. The "gold standard" method is chemiluminescence (Body et al. 1995; Kavanagh and Pearl 1995), but other more economical and "user-friendly" monitors are becoming commercially available.

Dose recommendations for inhaled NO are variable and circumstance dependent, but most suggestions lie in the region of 0.1–40 ppm, with recent emphasis on the lower concentrations (Rossaint et al. 1993; Puybasset et al. 1994; Kavanagh and Pearl 1995). Inhaled NO effectiveness may be enhanced if NO is combined with adjunctive agents such as almitrine bismesylate (Wysocki et al. 1994; Lu et al. 1995).

In summary, at present NO inhalation is a promising therapy for some patients with reversible lung disease. However, its present use with human and veterinary patients continues to be considered in the experimental phase.

Trace Concentrations of Inhalation Anesthetics: Occupational Exposure

Inhalation anesthetics are unique among the anesthetic drugs because they are administered, and in large part removed from the body, via the lungs. They are used widely for the anesthetic management of animals in part because their pharmacokinetic characteristics favor predictable and rapid adjustment of anesthetic depth. In addition, a special apparatus is usually used to deliver the inhaled agents. This helps minimize patient morbidity or mortality because it facilitates accurate and controlled anesthetic delivery, lung ventilation, and improved arterial oxygenation.

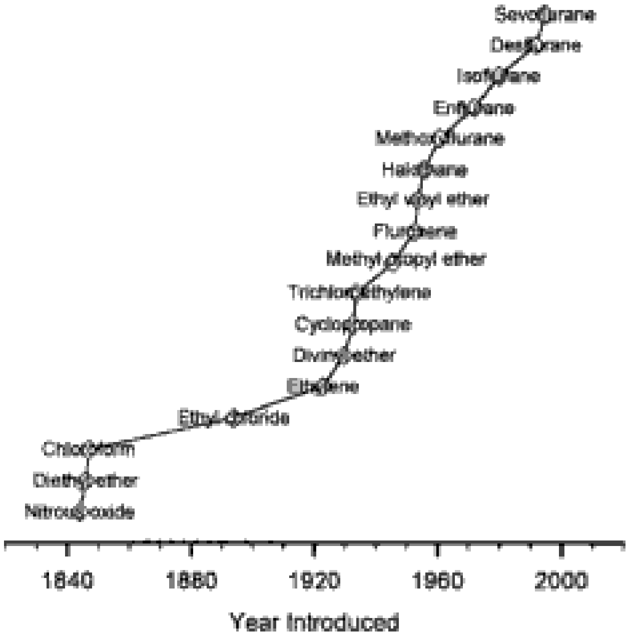

FIG. 11.1—Inhalation anesthetics introduced for widespread clinical use. (Adapted from Eger 1985a; reprinted with permission from Steffey 1995.)

The search for anesthetic agents with ever greater safety and fewer side effects is ongoing. Over the 150 years that inhalation anesthesia has been used in clinical practice, fewer than 20 agents have actually been introduced and approved for general use with patients (Fig. 11.1). Fewer than 10 of these have had any history of widespread clinical use in veterinary medicine, and only 5 are of current clinical importance in North America. This chapter will focus on this last group of anesthetics (Table 11.1). The group includes halothane and isoflurane, which together are the most widely used inhaled anesthetics. In addition, nitrous oxide (N_2O), methoxyflurane, and enflurane enjoy varying, but lesser, degrees of popularity. Unfortunately, none of these is the ideal inhalation anesthetic. An ideal agent would have characteristics that include a stable shelf life without preservatives and compatibility with existing delivery equipment. It would be inexpensive to purchase, nonflammable, and easily vaporized under

  - Fluroxene
  - Trichloroethylene

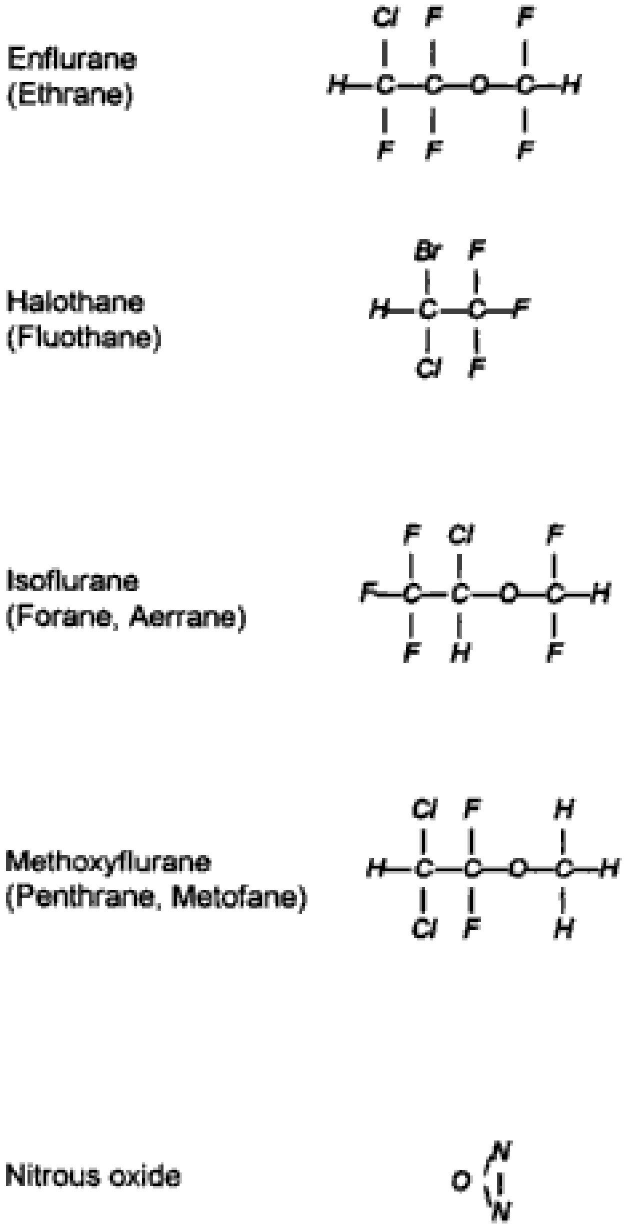

FIG. 11.2—Chemical structure of inhalation anesthetics in current use for animals. Trade names are given in parentheses.

ambient conditions. Such an agent would have a low blood solubility to foster rapid changes in anesthetic depth and permit rapid, controlled recovery from anesthesia. The ideal agent would be very potent, thereby allowing anesthesia at low inspired concentrations and maximizing flexibility of adjustments of inspired oxygen concentration. There would be no cardiopulmonary depression; the agent would not be irritating to airways and would be compatible with catecholamines and other vasoactive drugs. Finally, it would produce good skeletal muscle relaxation, resist degradation in the body, and be nontoxic to kidneys, liver, and gut.

Since the search for the ideal agent continues, new anesthetics are found. A few years ago desflurane and sevoflurane were released in the U.S. for general clinical use with human patients. Although at this time these agents have only very limited direct impact on the anesthetic management of animals, a review of the characteristics of these agents here is important.

A third group is comprised of agents that once enjoyed variable popularity for veterinary application (Table 11.1). These agents are no longer broadly used in clinical circumstances so they will not be discussed beyond brief mention of examples here. Data of typical contemporary interest regarding their action in species of clinical importance to veterinary medicine are generally lacking, but readers interested in further information on agents in this group are referred to early editions of pharmacology (Booth and McDonald 1988) and veterinary anesthesia textbooks (Soma 1971; Hall 1971; Lumb and Jones 1973; Short 1987). This third group of anesthetics includes agents like chloroform and cyclopropane. These agents have long been discarded for general use in human and veterinary medical practice because they cause liver failure (chloroform) or are explosive (cyclopropane). Diethyl ether, on the other hand, was widely used for clinical anesthetic management of human patients and a variety of animals up to about 20 years ago but then was largely replaced by newer agents because it is flammable (Duncalf 1982). This characteristic negates its use in the environment of the modern operating room, which ordinarily includes a variety of electrical surgical support (e.g., electrocautery), anesthetic delivery, and patient monitoring and ventilating devices. However, it is still used in some laboratory situations and in selected clinical circumstances, especially outside North America. Accordingly, there is continued justification to provide a brief overview of its pharmacology.

PHYSIOCHEMICAL CHARACTERISTICS. The their physical properties are important determinants of their actions and safety of administration. Consequently, brief discussion of aspects of Figs. 11.2 and 11.3 and Tables 11.2 and 11.3 is appropriate because

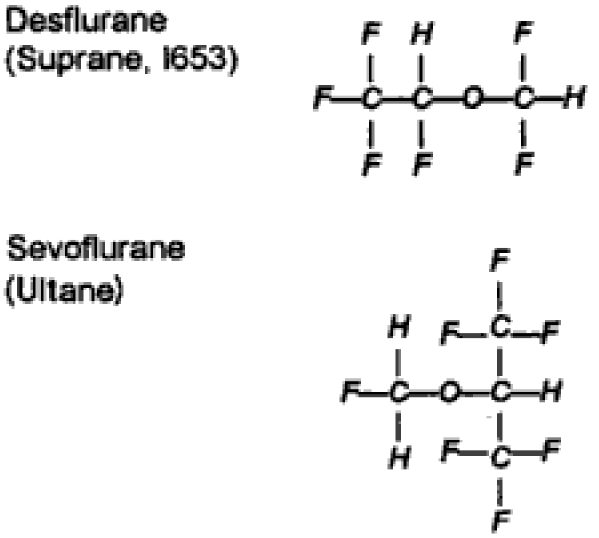

FIG. 11.3—Chemical structure of two new inhalation anesthetics. Trade name is given in parentheses.

physiochemical characteristics determine and/or influence practical considerations such as how the agents are supplied by the manufacturer (e.g., as a gas or as a liquid), the stability of the anesthetic molecule to degradation by physical factors (e.g., heat, light) and by substances it contacts during use (e.g., metal, soda lime). The equipment necessary to safely deliver the agent to the patient (e.g., vaporizer, breathing apparatus) is influenced by some of these properties as are the agent's uptake by the patient and its distribution within and elimination (including potential for metabolic breakdown) from the patient.

Chemical Characteristics. All contemporary inhalation anesthetics are organic compounds except nitrous oxide (N_2O) (Table 11.1). Agents of current interest are further classified as either aliphatic (i.e., straight or branch chained) hydrocarbons or ethers (i.e., two organic radicals [R] attached to an atom of oxygen; the general structure is R–O–R).

In the continued search for a less reactive, more potent, nonflammable inhalation anesthetic, focus on halogenation (i.e., addition of fluorine, chlorine, or bromine; iodine is least useful) of these compounds has predominated. Chlorine and bromine especially convert many compounds of low anesthetic potency to more potent drugs. Historically, interest in fluorinated derivatives was delayed until the 1940s because of difficulties in synthesis, and thus quantities available for study were limited. Methods of synthesis, although difficult, have improved considerably and have facilitated discovery of new agents (Fig. 11.1). Interestingly, organic fluorinated compounds are a group of extreme contrasts: some are toxic, others are not; some are extremely inert, others are highly reactive. In some anesthetics fluorine is substituted for chlorine or bromine to improve stability but at the expense of reduced anesthetic potency and solubility.

Halothane (Fig. 11.2) is a halogenated aliphatic saturated hydrocarbon (ethane). Predictions that halogenated structure would provide nonflammability and molecular stability encouraged the development of halothane in the early 1950s. However, soon after clinical introduction it was observed that the concurrent presence of halothane and catecholamines increased the incidence of life-threatening cardiac arrhythmias, especially in human patients. An ether linkage in the molecule favors a reduced incidence of cardiac arrhythmias. Consequently, this chemical structure is a predominant characteristic of all agents developed or proposed for clinical use since the introduction of halothane (Figs. 11.2 and 11.3).

Despite many favorable characteristics and improvements over earlier anesthetics, including improved chemical stability, halothane is susceptible to decomposition. Accordingly, halothane is stored in dark bottles, and a very small amount of a preservative, thymol, is added to it to retard breakdown. Thymol is much less volatile than halothane and over time collects within the devices used to control delivery of the volatile anesthetic (i.e., vaporizers) and causes them to malfunction. To achieve greater molecular stability, fluorine is substituted for chlorine or bromine in the anesthetic molecule. This chemical manipulation adds shelf life to the substance and negates the need for additives such as thymol. Unfortunately, the fluorine ion is also toxic to some tissues (e.g., kidneys), which is of substantial concern if the parent compound (e.g., methoxyflurane, enflurane, sevoflurane; Figs. 11.2, 11.3) is not resistant to metabolism.

Physical Characteristics. In simplest form the administration of inhalation anesthetics requires a carrier gas that must include oxygen, a source of anesthetic, and a patient breathing circuit. For very small animals (e.g., laboratory rodents or small birds) this may mean nothing more than placing the animal in a closed air-filled chamber that contains a cotton pledget saturated with liquid anesthetic (e.g., methoxyflurane). With larger animals and/or to provide more controlled delivery of anesthetic and O_2 it is more appropriate to use specialized equipment. Such equipment, though more complex, greatly improves the safety of the anesthetic technique. It includes what is commonly referred to as an anesthetic machine, one or more vaporizers, and a patient breathing circuit. The anesthetic machine with two vaporizers attached is shown in schematic form in Fig. 11.4. Extensive reviews of anesthetic equipment are available (Short 1987; Dorsch and Dorsch 1984; Andrews 1990 Thurmon et al. 1996).

The chain of events whereby anesthetic is transferred under control from a container to sites of action in the central nervous system (CNS) involves many physical characteristics that can be quantitatively described (Tables 11.2–11.5). The practical clinical applications of these quantitative descriptions will be briefly reviewed here. More in-depth background information is available elsewhere (Lowe and Ernst 1981; Hill 1980; Eger 1990; Butterworth and Strichartz 1990).

The physical characteristics of importance to this review are divided into two general categories; those that determine the means by which the agents are administered and those that help determine their kinetics in the body. This information is applied in the clinical manipulation of anesthetic induction and recovery and in facilitating changes in anesthetic levels in timely fashion.

PROPERTIES DETERMINING METHODS OF ADMINISTRATION. A variety of physical properties determine the means by which inhalation anesthetics are administered. These include molecular weight, boiling-point, liquid density (specific gravity), and vapor pressure.

Gas versus Vapor. Inhalation anesthetics are either gases or vapors. In relation to inhalation anesthetics the term "gas" refers to an agent, like N_2O (or cyclopropane), that exists in its gaseous form at room temperature and sea-level pressure. The term "vapor" indicates the gaseous state of a substance that at ambient temperature and pressure is a liquid. With the exception of N_2O, all the contemporary and new anesthetics fall into this category. Desflurane (Table 11.3), one of the new volatile liquids, comes close to the transition stage and has some unique (among the inhalation anesthetics) properties, to be discussed later in this chapter.

Regardless whether inhalation agents are supplied as a gas or volatile liquid under ambient conditions, the same physical principles apply to each agent when in the gaseous state.

Methods of Description. Quantities of inhalation anesthetic agent are usually characterized by one of three methods: pressure (e.g., in mm Hg), concentration (in volumes %), or mass (in mg or g). The form most familiar to clinicians is that of concentration (e.g., *X*% of agent A in relation to the whole gas mixture). Modern monitoring equipment samples inspired and expired gases and provides concentration readings for inhalation anesthetics. Precision vaporizers used to control delivery of inhalation anesthetics are calibrated in percentage of agent, and effective doses are almost always reported in percentages. Pressure is also an important way of describing inhalation anesthetics and will be discussed next. Finally, the molecular weight and agent density are used in many calculations to convert from liquid to vapor volumes and mass (Hill 1980).

Vapor Pressure. The vapor pressure of an anesthetic is a measure of its ability to evaporate; i.e., it is a measure of the tendency for molecules in the liquid state to enter the gaseous (vapor) form. The vapor pressure of a volatile anesthetic drug must at least be sufficient to provide enough molecules of anesthetic in the vapor state to produce anesthesia at ambient conditions. The *saturated vapor pressure* represents a maximum concentration of molecules in the vapor state that can

exist for a given liquid at each temperature. The saturated vapor concentration can be easily determined by relating the vapor pressure to the ambient pressure. Using halothane and associated information from Table 11.2 as an example, we see that a maximal concentration of 32% halothane is possible under usual operating-room conditions; that is, 244/760 × 100 = 32%, where 244 mm Hg is the vapor pressure at 20° C and 760 mm Hg is the barometric pressure at sea level. Thus, other variables considered constant, the greater the vapor pressure, the greater the concentration of the drug deliverable to the patient. Therefore, again from Table 11.2, halothane, for example, is more volatile than methoxyflurane under similar conditions.

Boiling Point. The boiling point of a liquid is defined as the temperature at which the vapor pressure of the liquid is equal to the atmosphere pressure. Customarily, the boiling temperature is stated for the standard pressure of 760 mm Hg. The boiling point decreases with increasing altitude since the vapor pressure does not change but the barometric pressure decreases.

The boiling point of N_2O is –89° C (Table 11.2) at 1 atmosphere pressure, sea level. It is thus a gas under operating-room conditions. Because of this it is distributed for clinical purposes in steel tanks compressed to the liquid state at about 750 psi (pounds per square inch; 750 psi/14.9 psi [1 atmosphere] = 50 atmospheres). As the N_2O gas is drawn from the tank, liquid N_2O is vaporized, and the overriding gas pressure remains constant until no further liquid remains in the tank. At that point only N_2O gas remains, and the gas pressure decreases from this point as remaining gas is vented from the tank. Consequently, the weight of the N_2O plus tank rather than the gas pressure within the tank is a more accurate guide to the remaining contents of the tank (Haskins and Sansome 1979).

Desflurane, the newest clinically available volatile anesthetic, poses an interesting problem since its boiling point (Table 11.3) is near room temperature. This characteristic accounted for an interesting engineering challenge in developing an administration device (i.e., vaporizer) for routine use in the relatively constant environment of the operating room and limits its use to a narrow range of circumstances commonly encountered in veterinary medical applications. For example, because of its low boiling point, even evaporative cooling has large influences on the vapor pressure and thus on the vapor concentration of gas mixtures delivered to the patient.

PROPERTIES INFLUENCING DRUG KINETICS: SOLUBILITY. Anesthetic gases and vapors dissolve in liquids and solids. The solubility of an anesthetic is a major characteristic of the agent and has important clinical ramifications. For example, anesthetic solubility in blood and body tissues is a primary factor in the rate of uptake and distribution within the body. It is therefore a primary determinant of the speed of anesthetic induction and recovery. Solubility in lipids bears a strong relationship to anesthetic potency, and the tendency to dissolve in anesthetic delivery components such as rubber influences equipment selection and other aspects of anesthetic management.

The extent to which a gas will dissolve in a given solvent is usually expressed in terms of its *solubility coefficient* (Table 11.4). With inhalation anesthetics solubility is most commonly expressed as a partition coefficient (PC). Other expressions of solubility include the Bunson and Ostwald solubility coefficients (Hill 1980; Eger 1974).

The PC is the concentration ratio of an anesthetic in two solvent phases, for example, blood and gas. It thus describes the affinity or capacity of an anesthetic for one solvent phase relative to another, that is, how the anesthetic will *partition* itself between two phases after equilibrium has been reached. Anesthetic gas movement occurs because of a partial pressure difference in the two phases so that when there is no longer any anesthetic partial pressure difference between the two phases, there is no longer any net movement of anesthetic in either phase direction, and equilibrium has been achieved. Solvent/gas PCs are summarized in Table 11.4. Values noted in this table are for human tissues since they are the most widely valued and thus the data are available in the anesthesia literature. Rubber/gas and plastic/gas PCs are given in Table 11.5. It is important to emphasize that many factors besides species can alter anesthetic agent solubility (Eger 1974; Mapleson et al. 1972; Eger and Eger 1985; Lerman et al. 1986). Perhaps most notable after the nature of the solvent is that of temperature.

Of all the PCs that have been described or are of possible interest, two are of particular importance in the practical understanding of anesthetic management. They are the blood/gas and the oil/gas solubilities.

Blood/Gas Partition Coefficient. The blood/gas solubility (Table 11.4) is a measure of the speed of anesthetic induction, recovery, and change of anesthetic levels. For example, other factors considered constant, the lower the blood/gas PC, the more rapid the anesthetic induction or rate of change of anesthetic level in response to a stepwise change in anesthetic delivery. Further information regarding the influence of anesthetic blood solubility on practical aspects of anesthetic management is presented in the section on pharmacokinetics.

Oil/Gas Partition Coefficient. The oil/gas PC is another solubility characteristic of clinical importance (Table 11.4). This PC describes the ratio of concentration of an anesthetic in oil (in this case olive oil is the generally agreed upon standard) and gas phases at equilibrium. The oil/gas PC correlates directly with anesthetic potency (see section in this chapter titled Anesthetic Dose: The Minimum Alveolar Concentration) and describes the capacity of lipids for anesthetic.

Other Partition Coefficients. Solubility characteristics for tissues (Table 11.4) and other media like rubber and plastic (components of anesthetic delivery equipment; Table 11.5) are also important. For example, tissue solubility determines in part the quantity of anesthetic removed from the blood to which it is exposed. The higher the tissue solubility, the longer it will take to saturate the tissue with anesthetic agent. Thus, other things considered equal, agents very soluble in tissues will require a longer period for induction and recovery. If the rubber goods are of substantial amount in the apparatus used to deliver the anesthetic to the patient and anesthetic agent solubility in rubber is large, the amount of uptake of anesthetic agent by the rubber may be of clinical significance.

PHARMACOKINETICS: UPTAKE AND ELIMINATION OF INHALATION ANESTHETICS. The aim in administering an inhalation anesthetic to a patient is to achieve an adequate partial pressure, or tension, of anesthetic (P_{anes}) in the brain to cause a desired level of anesthesia. Anesthetic depth varies directly with P_{anes} in brain tissue. The rate of change of anesthetic depth is of obvious clinical importance and is directly dependent upon the rate of change in anesthetic tensions in the various media in which it is contained before reaching the brain. This section will not provide an extensive review of these principles. If more information is desired, readers are directed to reviews by Eger (1974, 1990), Butterworth and Strichartz (1990), Mapleson (1989), and Steffey (1994, 1991, 1995).

Movement of molecules of inhalation anesthetics, like O_2 and CO_2, occurs down partial pressure gradients (Fig. 11.5). Gases move from regions of higher tension to those of lower tension until equilibrium (i.e., equal pressure in the two media) is established. Thus, during anesthetic induction, the P_{anes} at its source, say in the vaporizer, is high (which, in turn as we recall, is dictated by the vapor pressure) and is progressively less as anesthetic travels from vaporizer to patient breathing circuit, from circuit to lungs, from lungs to arterial blood, and, finally, from arterial blood to body tissues (e.g., brain; Fig. 11.5). Of these, the alveolar partial pressure (P_A) of anesthetic is most crucial to our further understanding. The reasoning for this is as follows. The brain is very rich in blood supply, and the anesthetic in arterial blood (P_aAnes) rapidly equilibrates with brain (P_{brain}Anes). Usually gas exchange at the alveolar level is sufficiently efficient when the P_aAnes is close to P_AAnes. Thus, the P_{brain}Anes closely follows P_AAnes, and controlling the P_AAnes is a reliable indirect way for controlling P_{brain}Anes and anesthetic depth.

At this point it may also be helpful to recall that although the partial pressure of anesthetic is of primary importance, we frequently define clinical dose of an inhaled anesthetic in terms of concentration (*C;* i.e., volumes %). As previously noted, this is because it is common practice for the clinician to regulate and/or measure respiratory and anesthetic gases in volumes %. In addition, in the gaseous phase the relationship between the P_{anes} and the C_{anes} is a simple one:

$$P_{anes} = \text{fractional anesthetic concentration} \times \text{total ambient pressure}$$

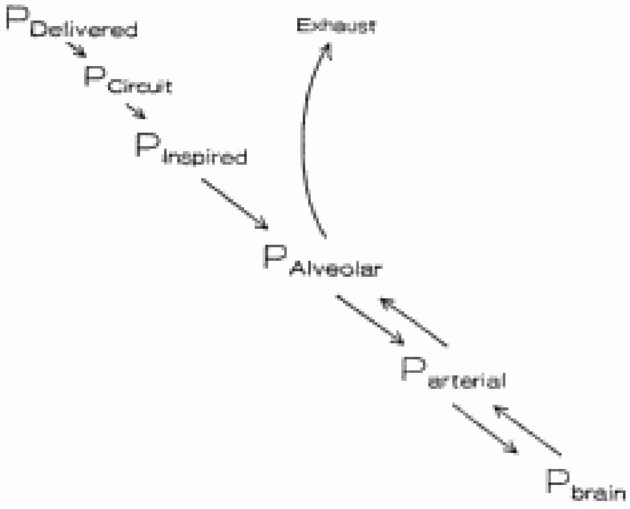

FIG. 11.5—The flow pattern of inhaled anesthetic agents during anesthetic induction and recovery. Inhalation anesthesia may be viewed as the development of a series of partial pressure (tension) gradients. During induction there is a high anesthetic tension in the vaporizer that decreases progressively as the flow of anesthetic gas moves from its source to the brain. Some of these gradients are easily manipulated by the anesthetist; others are not or are done so with difficulty. (From Steffey 1994, with permission of the publishers.)

The fractional anesthetic concentration is of course C_{anes}/100. However, as we reviewed in the section above, in the blood or tissue phases, for example, the actual quantity of anesthetic vapor contained in this solvent phase depends on both the P_{anes} and the anesthetic solubility (or PC) in the solvent phase. Consequently, at equilibrium, the partial pressure in all phases will be equal, but the concentration will vary.

The P_A of anesthetic is a balance between anesthetic input (i.e., delivery to the alveoli) and loss (uptake by blood and body tissues) from the lungs (Fig. 11.5). A rapid rise in P_A of anesthetic is associated with a rapid anesthetic induction or change in anesthetic depth. Factors that contribute to a rapid change in P_A of anesthetic are summarized in Fig. 11.6.

Delivery to the Alveoli. Delivery of anesthetic to the alveoli and therefore the rate of rise of the alveolar concentration or fraction (F_A) toward the inspired concentration or fraction (F_I) depend on the inspired anesthetic concentration itself and the magnitude of alveolar ventilation. Increasing either one of these or both increases the rate of rise of the P_A of anesthetic; that is, other things considered equal, there is an increase in speed of anesthetic induction or change in anesthetic level.

- **A. Increased alveolar delivery of anesthetic**
  - **1. Increased inspired anesthetic concentration**
    - **a. Increased vaporization of agent**
    - **b. Increased vaporizer dial setting**
    - **c. Increased anesthetic laden fresh gas inflow to the patient breathing circuit**
    - **d. Decreased gas volume of patient breathing circuit**
    - **e. Vaporizer positioned in a patient rebreathing circuit**
  - **2. Increased alveolar ventilation**
    - **a. Increased minute ventilation**
    - **b. Decreased ventilation of respiratory system dead space**
- **B. Decreased removal of anesthetic from the alveoli**
  - **1. Decreased blood solubility of anesthetic**
  - **2. Decreased cardiac output**
  - **3. Decreased alveolar-venous anesthetic gradient**

FIG. 11.6—Factors related to a rapid change in alveolar anesthetic tension (Lockhart et al. 1991a; modified from Steffey 1994).

INSPIRED CONCENTRATION. The inspired concentration has a number of variables controlling it. First of all, the upper limit of inspired concentration is dictated by the agent vapor pressure, which in turn is dependent on temperature. This may be especially important considering the breadth of veterinary medical application of inhaled anesthesia and methods of vaporizing volatile anesthetics under widely diverse conditions (e.g., some environmental conditions are quite hostile).

Characteristics of the patient breathing system in use can also be a major factor in generating a suitable inspired concentration under usual operating-room conditions. Characteristics of special importance include the volume of the system, the amount of rubber or plastic in the system, the position of the vaporizer relative to the breathing circuit (i.e., within or outside the circuit), and the fresh gas inflow to the patient breathing circuit.

The solubility of especially some anesthetics (e.g., methoxyflurane; Table 11.5) in rubber and plastic will also delay development of an appropriate inspired anesthetic concentration. The loss of anesthetic to these equipment "sinks" serves to increase the apparent volume of the anesthetic circuitry and may, in some cases, be clinically important (e.g., use of rubber hoses and a large rubber rebreathing bag on circuits designed for anesthetic management of horses).

ALVEOLAR VENTILATION. An increase in alveolar ventilation increases the rate of delivery of inhalation anesthetic to the alveoli. If unopposed, alveolar ventilation would rapidly increase the alveolar concentration of anesthetic so that within minutes the alveolar concentration would equal the inspired concentration. However, in reality the input created by alveolar ventilation is countered by absorption of anesthetic into blood. Predictably, hypoventilation reduces the rate at which the alveolar concentration increases over time compared to the inspired concentration; that is, anesthetic induction is slowed. Alveolar ventilation is altered by changes in anesthetic depth (increased depth usually means decreased ventilation), mechanical ventilation (usually increased ventilation), or changes in dead-space ventilation (i.e., for constant minute ventilation, a decrease in dead-space ventilation results in an increase in alveolar ventilation).

Removal from the Alveoli: Uptake by Blood. As noted by Eger (1990) anesthetic uptake is the product of three factors: solubility (*S*; the blood/gas solubility, Table 11.4), cardiac output (CO), and the difference in the anesthetic partial pressure between the alveoli and venous blood returning to the lungs ($P_A - P_v$; expressed in mm Hg); that is,

$$\text{Uptake} = S \cdot \text{CO} \cdot [(P_A - P_v)/P_{bar})],$$

where P_{bar} = barometric pressure in mm Hg. Note that if any of these three factors equals zero, there is no further uptake of anesthetic by blood.

SOLUBILITY. The solubility of an inhalation anesthetic in blood and tissues is characterized by its partition coefficient (PC; Table 11.4).

Compared to an anesthetic agent with high blood solubility (PC), an agent with low blood solubility should be associated with a more rapid equilibration between tissue phases because a large amount of the highly soluble anesthetic must be dissolved in the blood before equilibrium is reached with the gas phase. In the case of the agent with a high blood/gas PC, the blood acts like a large "sink" into which the anesthetic is poured, and accordingly blood is "reluctant" to give up agent to other tissues (like the brain). For purposes of the present discussion, the blood only serves as a conduit for drug delivery to brain and as such can be visualized as a large or small pharmacologically inactive reservoir that is interposed between the lungs and the agent's site of desired pharmacological activity (i.e., brain). Therefore, an anesthetic agent with a low blood/gas PC is usually more desirable than a soluble

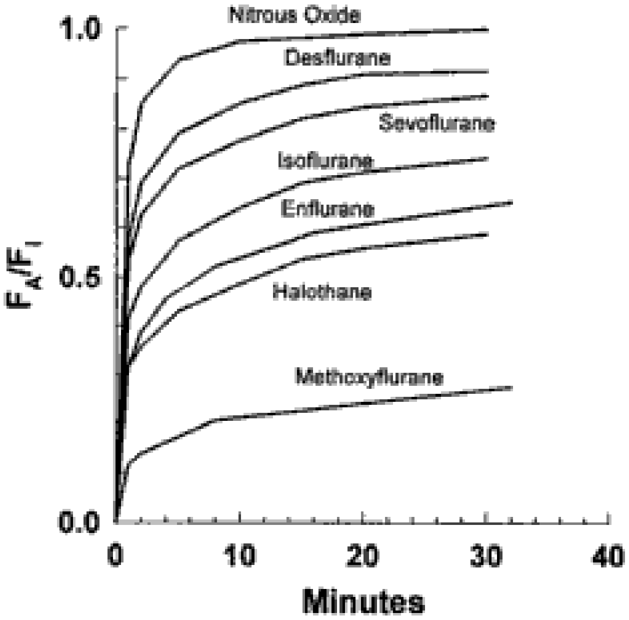

FIG. 11.7—The rise in the alveolar (F_A) anesthetic concentration toward the inspired (F_I) concentration. Note the rise is most rapid with the least soluble anesthetic, N_2O, and slowest with the most soluble anesthetic, methoxyflurane. All data are from studies of humans. The curves are redrawn from Eger 1985a, 1992.

agent, because it is associated with (1) a more rapid anesthetic induction (i.e., more rapid rate of rise in alveolar concentration during induction; Fig. 11.7); (2) more precise control of anesthetic depth (i.e., alveolar concentration during the anesthetic maintenance phase of anesthesia); and (3) a more rapid elimination of anesthetic and recovery from anesthesia (i.e., a rapid decrease in alveolar concentration during the anesthetic recovery phase).

CARDIAC OUTPUT. The amount of blood flowing through the lungs and on to body tissues (cardiac output, or CO) also influences anesthetic uptake from the lungs. The greater the CO, the more blood passing through the lungs carrying away anesthetic from the alveoli. Thus, a large CO, like increased anesthetic agent blood solubility, delays the alveolar rise of P_{anes}. Patient excitement is an example in which a relatively large CO is anticipated. Conversely, a reduced CO should be anticipated with a patient in shock. Such a situation is associated with a relative increase in the rate of rise of the P_A of anesthetic and makes anesthetic induction more risky.

ALVEOLAR TO VENOUS ANESTHETIC PARTIAL PRESSURE DIFFERENCE. The magnitude of difference in anesthetic partial pressure between the alveoli and venous blood is related to the amount of uptake of anesthetic agent by tissues. Not surprisingly, the largest gradient occurs during induction. Once the tissues no longer absorb anesthetic (i.e., equilibrium between the two phases is reached), there is no longer any uptake of anesthetic agent from the lungs (i.e., the venous blood returning to the lungs contains as much agent as when it left the lungs). The changes in gradient in between these extremes result from the relative distribution of CO. In this regard it is important to recognize that roughly 70–80% of the CO is normally directed to only a small volume of body tissues in a lean individual (Webb 1985; Staddon et al. 1979). That is, tissues such as brain, heart, hepatoportal system, and kidneys represent only about 10% of the body mass but normally receive about 75% of the total blood flow each minute. As a result these highly perfused tissues equilibrate with arterial anesthetic tension fairly rapidly (actual timing is influenced by agent solubility). Since the venous anesthetic tension equals that in the tissue within 10–15 minutes, about 75% of the blood returning to the lungs is the same as the alveolar tension. This presumes there has been no change in the mean time in arterial tension. Thus uptake is reduced. Skin and muscle compose the major bulk of the body (about 50% in humans) but at rest receive only about 15–20% of the CO, so saturation of this tissue group takes up to a few hours to accomplish. Fat is a variable component of body bulk and receives only a small proportion of blood flow. Consequently, anesthetic saturation of this tissue group is very slow, especially given that all anesthetics are considerably more soluble in fat than in other tissue groups (Table 11.4).

Other factors can further influence the magnitude of the alveolar-to-arterial anesthetic partial pressure gradient. They include abnormalities of lung ventilation/perfusion (Eger and Severinghaus 1964), loss of anesthetic via the skin (Stoelting et al. 1969; Fassoulaki et al. 1991; Lockhart et al. 1991b) and into closed gas spaces (Eger 1974, 1990, 1985b), and metabolism (Eger 1974, 1990).

Anesthetic Recovery. Recovery from inhalation anesthesia results from the elimination of anesthetic from the brain. This requires a decrease in alveolar anesthetic partial pressure (concentration), which in turn fosters a decrease in arterial and then brain anesthetic partial pressure (Fig. 11.5). Prominent factors accounting for recovery are the same as those for anesthetic induction. Therefore, factors such as alveolar ventilation, CO, and especially agent solubility play prominent roles in recovery from inhalation anesthesia. Indeed, the graphic curves representing the wash out of anesthetic from the alveoli versus time (Fig. 11.8) are essentially inverse of the wash-in curves seen earlier (Fig. 11.7). That is, the wash out of the less soluble anesthetics is high at first, then rapidly declines to a lower output level that continues to decrease but at a slower rate.

The output with the more soluble agent is also high at first, but the magnitude of decrease in alveolar anesthetic concentration is less and only more gradually decreases with time (Fig. 11.8). Thus recovery from the two newest agents, desflurane and sevoflurane, is faster than with isoflurane and even more so than the older agents (Eger and Johnson 1987; Frink et al. 1992).

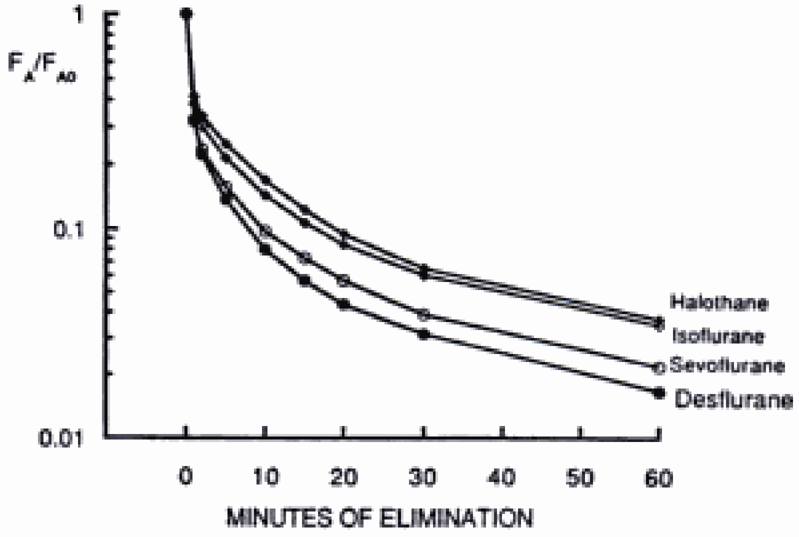

FIG. 11.8—The fall in alveolar (F_A) concentration relative to the alveolar concentration at the end of anesthesia (F_{A0}). Note that the newest, most insoluble volatile anesthetic, desflurane, is eliminated in humans more rapidly than the other contemporary potent anesthetics. Not shown is information for methoxyflurane—if present, the curve for methoxyflurane would appear above that for halothane. (From Eger 1992; reprinted with permission.)

A factor that is important in the rate of recovery but not during the induction period is the duration of anesthesia. Because there is a greater reserve in the body of a highly soluble agent like methoxyflurane after a prolonged administration, its alveolar concentration will be slow to fall in comparison to a less soluble agent like isoflurane.

Other factors that are important to varying but smaller degrees to inhalation anesthetic elimination from the body include percutaneous loss (Stoelting and Eger 1969; Lockhart et al. 1991b; Fassoulaki et al. 1991; Cullen and Eger 1972) and intertissue diffusion of agents (Carpenter et al. 1987, 1986a). Metabolism may also play a small role with some inhalation anesthetic agents (e.g., methoxyflurane and perhaps even halothane; Baden and Rice 1994; Carpenter et al. 1986b, 1987; Cahalan et al. 1981), especially in cases of clinically unusual, prolonged anesthesia. No appreciable effect on recovery by metabolism is expected for isoflurane, desflurane and sevoflurane.

Biotransformation. Inhalation anesthetics are not chemically inert (Van Dyke et al. 1964). They undergo varying degrees of metabolism (Table 11.6), primarily in the liver but also to lesser degrees in the lung, kidney, and intestinal tract (Stier et al. 1964; Rehder et al. 1967; Holaday et al. 1970; Baden et al. 1994; Mazze et al. 1989). The importance of this is twofold. First, in a very limited way with older anesthetics, metabolism may facilitate anesthetic recovery (supra vide). Second and more important is the potential for acute and chronic toxicities by intermediary or end metabolites of inhalation agents on, especially, kidneys, liver, and reproductive organs (Baden and Rice 1994; Mazze and Fujinaga 1989).

TABLE 11.6—Biotransformation of inhalation anesthetics in humans

Anesthetic	Anesthetic recovered as metabolites (%)	Reference
Methoxyflurane	50	Holaday et al. 1970
Halothane	20-25	Cascorbi et al. 1970; Rehder et al. 1967
Sevoflurane	3	Eger 1994
Enflurane	2.4	Chase et al. 1971
Isoflurane	0.17	Holaday et al. 1975
Desflurane	0.02	Eger 1994
Nitrous oxide	0.004	Hong et al. 1980a

For further information on the biotransformation of inhalation anesthetics and for details regarding individual anesthetic agents, see reviews by Baden and Rice (1994) and Mazze and Fujinaga (1989).

Anesthetic Dose: The Minimum Alveolar Concentration. In 1963 Merkel and Eger described what has become the standard index of anesthetic potency for inhalation anesthetics: MAC (Merkel and Eger 1963). MAC is the minimum alveolar concentration of an anesthetic that prevents gross purposeful movement in 50% of subjects exposed to a supramaximal noxious stimulus. Thus, MAC corresponds to the effective dose-50, or ED_{50}; half of the subjects are anesthetized and half are not. The dose that corresponds to the ED_{95} (95% of the individuals are anesthetized), at least in humans, is 20–40% greater than MAC (De Jong and Eger 1975); and 2.0 times the MAC (i.e., 2 MAC) represents a deep level of anesthesia, in some cases even

TABLE 11.7—The minimum alveolar concentration (MAC) of inhalation anesthetics

Anesthetic	Bird	Cat	Dog	Horse	Human
Methoxyflurane	—	0.23	0.29	0.28	0.16
Halothane	1.04 (duck)	1.04	0.87	0.88	0.74
Isoflurane	1.30 (duck)	1.63	1.30	1.31	1.15
Enflurane	—	2.37	2.06	2.12	1.68
Sevoflurane	—	2.58	2.36	2.31	2.05
Desflurane	—	9.79	7.20	—	7.25
Nitrous oxide	220 (pigeon)	255	222	205	104

Note: Values are expressed in volumes % and selected from a review by Steffey (1995).

an anesthetic overdose. MAC values for contemporary inhalation anesthetics for a variety of animals commonly encountered in clinical veterinary medicine and humans are summarized in Table 11.7.

The anesthetic potency of an inhaled anesthetic is inversely related to MAC (i.e., potency = 1/MAC). From information presented above it also follows that MAC is inversely related to the oil/gas PC. Thus, a very potent anesthetic (e.g., methoxyflurane) has a low MAC value and a high oil/gas PC; an agent of low anesthetic potency (e.g., N_2O) has a high MAC and a low oil/gas PC.

A number of characteristics of MAC deserve emphasis (Eger 1974). MAC is defined in terms of a percentage of 1 atmosphere and therefore represents an anesthetic partial pressure at the anesthetic site of action (i.e., remember $P_a = C/100 \cdot P_{bar}$, where P_a stands for the partial pressure of the anesthetic in the gas mixture, C is the anesthetic concentration in volumes %, and P_{bar} is the barometric, or total, pressure of the gas mixture). Thus, although the concentration at MAC for a given agent may vary depending on ambient pressure conditions (e.g., sea-level vs. high-altitude locations), the anesthetic partial pressure at MAC would be the same.

Second, the A in MAC represents *a*lveolar concentration, not the inspired or delivered (as, e.g., from a vaporizer) concentration. This is important because as we reviewed above, after sufficient time for equilibration (i.e., minutes), alveolar partial pressure represents arterial and brain anesthetic partial pressures. In addition, the alveolar concentration is easily monitored with contemporary technology.

Finally, MAC is normally determined in healthy animals under controlled laboratory conditions in the *absence* of other drugs and other circumstances common to clinical use that may modify the requirements for anesthesia. Many factors can influence MAC (anesthetic requirement); some increase and some decrease MAC. (See reviews by Eger [1997] and Quasha et al. [1980]).

PHARMACODYNAMICS: ACTIONS AND TOXICITY OF THE INHALATION ANESTHETICS. Inhalation anesthetic agents influence vital organ function. Some actions are associated with the use of all agents while other actions are a special or prominent feature of one or a number of the agents. The differences in actions, and in particular undesirable actions, of specific anesthetic agents are major considerations when selecting one agent over another for clinical use. Undesirable actions also provide important impetus for development of new agents and/or anesthetic techniques.

The following review of the actions and toxicity of inhaled anesthetics draws from results of studies of many different species, including humans (in some cases humans are the most completely studied species). Species- or agent-specific reviews include those by Eger (1985a,b, 1993), Haskins and Klide (1992), and Steffey (1991, 1994, 1995).

It is important to stress that many variables commonly accompany anesthetic management of animals in both clinical and laboratory settings. These variables influence drug pharmacodynamics and may cause individuals to respond differently from test subjects that were studied under standardized conditions. Examples of such confounding variables include species, duration of anesthesia, noxious (surgical) stimulation, mechanical ventilation, coexisting disease, concurrent medications, and extremes of age.

Central Nervous System. Inhalation anesthetics produce a reversible generalized CNS depression for which the degree of depression is often described as depth of anesthesia. The mechanism of action of inhalation anesthetics is still poorly understood. (See Chap. 9.)

Several anesthetic agents in contemporary use have epileptogenic potential. Enflurane is most prominent in this regard among the potent inhalation anesthetics.

The fragile relationship between cerebral blood flow, intracranial pressure, and cerebral metabolic rate for oxygen is an especially important consideration in some types of patients. For example, an increase in intracranial pressure can reduce cerebral perfusion pressure to the extent that cerebral blood flow is reduced. This situation may in turn result in a reduction of oxygen delivery below that of metabolic oxygen demands required for brain vitality.

Inhalation anesthetics are potent vasodilators and tend to increase cerebral blood flow. Anesthetic-induced cerebral vasodilation and associated increases in cerebral blood flow increase intracranial pressure usually to a trivial extent in normal individuals but perhaps to a life-threatening extent in patients with preexisting reduced intracranial compliance (e.g., tumor, hemorrhage). In such cases isoflurane with hyperventilation (changes in arterial carbon dioxide tension, P_aCO_2, result in corresponding directional changes in cerebral blood flow; Drummond and Shapiro 1994) is preferred over a similar anesthetic management plan incorporating halothane.

Respiratory System. All contemporary inhalation anesthetics depress alveolar ventilation. As a consequence, the P_aCO_2 is increased in direct relation to anesthetic dose (MAC multiple; Fig. 11.9). The magnitude of P_aCO_2 is also species related (Fig. 11.10). In addition, the normal stimulation to ventilation caused by an increased P_aCO_2 and/or a low arterial oxygen tension (P_aO_2) is reduced (Pavlin and Su 1994; Knill and Gelb 1978).

Bronchospasm is associated with some diseases and other patient conditions and contributes to increased airway resistance. Among the volatile anesthetics, halothane appears to be the most effective bronchodilator (Coon and Kampine 1975; Klide and Aviado 1967).

Volatile inhalation anesthetics may affect reflex hypoxic pulmonary vasoconstriction and thereby contribute to a maldistribution of ventilation to perfusion and an increase in the alveolar-to-arterial partial pressure of oxygen and decrease in P_aO_2 (Pavlin and Su 1994; Marshall et al. 1984).

Cardiovascular System. All of the volatile inhalation anesthetics cause dose-dependent and drug-specific changes in cardiovascular performance. The mechanisms of cardiovascular effects are diverse but often include direct myocardial depression by the inhaled anesthetic and a directly or indirectly induced decrease in sympathoadrenal activity.

All of the volatile anesthetics decrease cardiac output, usually via a decrease in myocardial contractility (Pagel et al. 1991a, 1993; Eger 1985a; Warltier and Pagel 1992; Boban et al. 1992; Eisele 1985) and, in turn, stroke volume. The magnitude of change is dose related and dependent on agent (Eger 1985a; Steffey and Howland 1978b, 1980; Klide 1976; Steffey et al.

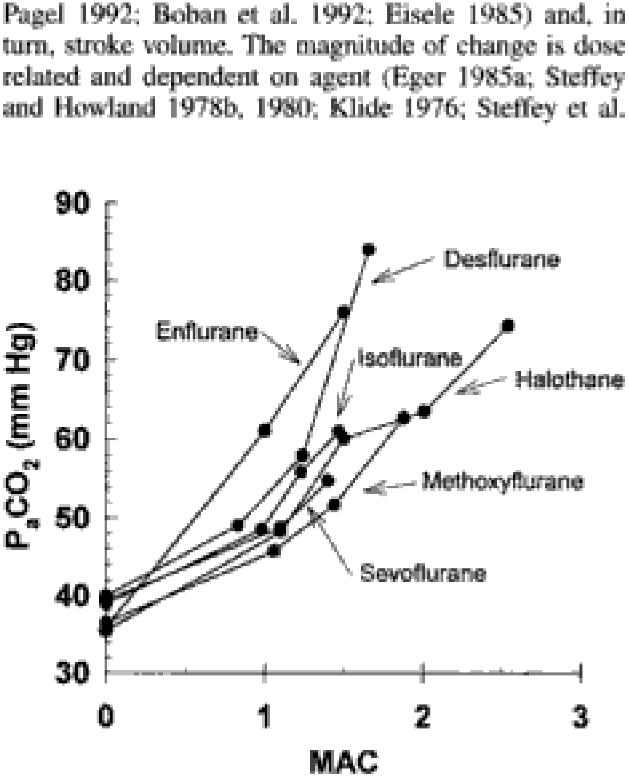

FIG. 11.9—A summary of the effects of contemporary volatile anesthetics on P_aCO_2 in humans, the species for which data are most complete. (Data from Lockhart et al. 1991a; Munson et al. 1966; Larson et al. 1969; Doi and Ikeda 1987; Calverley et al. 1978a; Fourcade et al. 1971.)

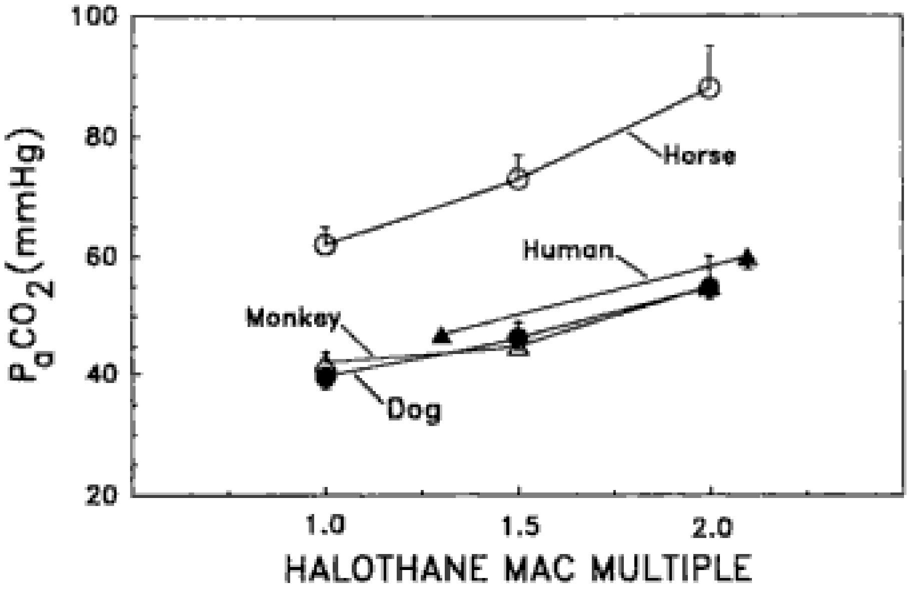

FIG. 11.10—The P_aCO_2 (mean ±1 SE; mm Hg) in spontaneously breathing, healthy dogs, horses, humans, and monkeys during halothane-oxygen anesthesia. The anesthetic dose is expressed as a multiple of the minimum alveolar concentration (MAC) for each species. (Reproduced from Steffey 1991, by permission.)

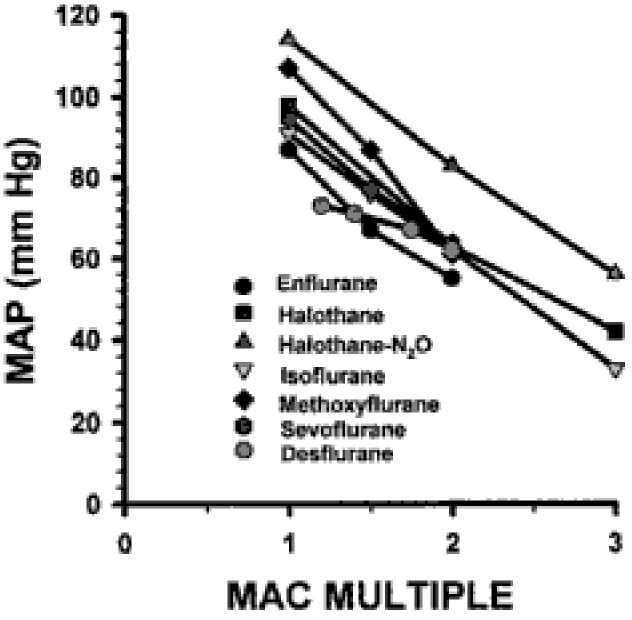

FIG. 11.11—Inhalation anesthetics cause a dose-dependent (expressed as multiples of MAC) decrease in mean arterial blood pressure (MAP) in dogs whose ventilation is mechanically controlled to produce eucapnia. (Data from Steffey et al. 1984; Steffey and Howland 1978b; Steffey et al. 1974b; Frink et al. 1992b; Merin et al. 1991.)

1984; Sommer 1987; Eger 1994; Merin et al. 1991; Weiskopf et al. 1988; Pagel et al. 1991b; Warltier and Pagel 1992). Arterial blood pressure is also decreased in a dose-related manner (Steffey et al. 1974b, 1974c, 1984; Steffey and Howland 1977, 1978b; Frink et al. 1992b; Merin et al. 1991) (Fig. 11.11). The decrease in arterial blood pressure is usually related to a decrease in cardiac output, but in some cases (agent or species related) a decrease in peripheral vascular resistance may also play an important but lesser role.

Inhalation anesthetics affect the cellular mechanisms of myocardial contraction at multiple steps. They decrease free calcium concentration (1) by interfering with Ca^{++} movement through the sarcolemma and by decreasing the availability and release of Ca^{++} from the sarcoplasmic reticulum and (2) by altering the sensitivity of regulatory and contractile proteins to available Ca^{++}. Halothane and enflurane are the most potent of the contemporary agents in this regard. These cellular effects are consistent with the rank order of agent-induced myocardial depression seen in the intact animal (Pavlin and Su 1994).

The distribution of blood flow to organs is altered during inhalation anesthesia (Eger 1985a; Warren and Webb 1986; Bernard et al. 1991; Haskins and Sansome 1979). For example, volatile anesthetics cause a dose-dependent increase in cerebral blood flow (supra vide) and decreases in blood flow to liver and kidneys (infra vide).

CARDIAC RHYTHM AND CATECHOLAMINES. Inhalation anesthetics may increase the automaticity of the myocardium (Price 1966). This effect is exaggerated by adrenergic agonists (Katz and Epstein 1968). Inhalation anesthetics, especially halothane, also may sensitize the heart to arrhythmogenic effects of catecholamines (Raventos 1956; Eger 1985a, 1994; Moore et al. 1993; Munson and Tucker 1975; Navarro et al. 1994; Joas and Stevens 1971; Weiskopf et al. 1989a; Johnston et al. 1976). Temporal changes in cardiovascular function have also been reported in a variety of animals during inhalation anesthesia (Steffey et al. 1987b,c,d, 1993a; Dunlop et al. 1987).

Liver. Hepatocellular injury may result as a general consequence of a reduction in hepatic blood flow or by direct anesthetic agent toxicity. Of the contemporary volatile agents, halothane is most often associated with direct hepatotoxicity.

Kidneys. All of the volatile anesthetics reduce renal blood flow and glomerular filtration rate in a dose-related manner. As a consequence, during anesthesia even healthy animals produce small volumes of concentrated urine. This response is a common finding regardless of the species studied. A transient increase in serum urea nitrogen, creatinine, and inorganic phosphate also may accompany inhalation anesthesia, especially if prolonged (Eger 1985a; Steffey et al. 1979, 1980; Stover et al. 1988; Pohl et al. 1988). In most cases the effects of inhalation anesthesia on renal function are rapidly reversed after anesthesia. Beyond these general responses, methoxyflurane is notable with regard to its potential for causing nephrotoxicity (see below).

Skeletal Muscle. The volatile anesthetics are associated with some small amount of skeletal muscle relaxation, likely a direct result of their CNS depression. They also enhance the muscle relaxation induced by the nondepolarizing neuromuscular blocking drugs that are sometimes used as adjuvants in the anesthetic management of patients.

Malignant hyperthermia, a life-threatening pharmacogenetic myopathy, is most commonly associated with halothane anesthesia. It is further discussed below.

Actions by Agent. Actions by agent will be discussed in this section; the volatile agents presented first, followed by the gaseous agent, N_2O. The agents can be divided into three groups based on broad use in veterinary medicine. Emphasis here is on the properties of halothane, isoflurane, and, later on, N_2O because they are currently the most widely used, and specific data derived from laboratory and clinical investigations are readily available. The second group includes methoxyflurane, enflurane, and diethyl ether. Methoxyflurane never was widely used for anesthetic management of large animals but is still (although increasingly less) selectively used for the management of small animals. Enflurane was never used a great deal for animals, especially in the clinical environment, and its current use overall is at best infrequent. Diethyl ether continues to have value in nonclinical aspects of animal anesthesia and locations outside North America. The remaining group of agents is composed of desflurane and sevoflurane. They are the newest agents; both now are approved for general use in humans in North America and elsewhere. Because chloroform is now used principally as a toxicological tool (to cause reproducible liver damage) and as an industrial solvent, its actions will not be covered.

HALOTHANE. *Halothane*, USP (Fluothane), a multihalogenated ethane, is a clear, volatile liquid. Introduction of halothane into clinical practice in 1957 represented a significant advance in anesthesia pharmacology, since the drug possesses characteristics of rapid induction and recovery, potency, and nonflammability, with minimal side effects (Brown and Sipes 1977). By 1960 halothane was the most popular potent anesthetic agent used in humans in the Western world. Human patients accept the anesthetic without difficulty because of its minimal unpleasant side effects. The most frequently used potent inhalation agent now used in humans is isoflurane.

BIOTRANSFORMATION. About 60–80% of administered halothane is eliminated unchanged in the exhaled breath. The remainder is eliminated via other routes either unchanged or as metabolites. Biotransformation of halothane occurs primarily in the liver; most as a result of the cytochrome P-450 system in the endoplasmic reticulum of the hepatocytes. It has been well established that a major metabolite of halothane metabolism in humans and animals is trifluoroacetic acid (Van Dyke and Wood 1975; Baden and Rice 1994). Other metabolites resulting from oxidative metabolism via the cytochrome P-450 pathway are inorganic chloride (Cl^-) and to a lesser extent bromine (Br^-). Since the bond for fluorine (F^-) is much stronger than for Cl^- or Br^-, little F^- is released. In humans, Br^- from halothane breakdown will induce headache, ataxia, lethargy, and EEG alterations (Tinker et al. 1976). In the dog (Pedersoli 1980) and horse (Rice and Steffey 1985b), serum bromide concentrations increase significantly during and following a period of halothane anesthesia.

An alternative route of halothane metabolism is via a reductive pathway requiring anaerobic conditions and the presence of an electron donor. Both Br^- and F^- are metabolites of this pathway (Baden and Rice 1994). An increase in halothane metabolism occurs in experimental animals when inducing agents such as phenobarbital and isoniazid are given prior to halothane (deGroot et al. 1982; Rice et al. 1987). Prolonged administration of low-dose halothane can also result in increased drug metabolism (Linde and Berman 1971; Ross and Cardell 1978). Such circumstances may have clinical consequences.

CENTRAL NERVOUS SYSTEM. Halothane depresses CNS function in a dose-related fashion until respiratory and cardiovascular collapse and death. The MAC for halothane in the dog is 0.9%; values for other species are given in Table 11.7.

Cerebral blood flow usually increases during halothane anesthesia and may result in an accompanying increase in cerebrospinal fluid pressure (Drummond and Shapiro 1994). Halothane is the most potent of the contemporary volatile anesthetics in this regard, making it a less desirable anesthetic for animals with preexisting space-occupying intracranial lesions and/or increased cerebrospinal fluid pressure. The cerebral metabolic oxygen consumption is reduced in dose-related fashion.

Shivering during recovery from halothane is common. Its cause is related to heat loss associated with general anesthesia and other ill-defined mechanisms (Sessler et al. 1988). Some drowsiness remains evident for several hours after halothane anesthesia even in ambulatory animals.

CARDIOVASCULAR SYSTEM. Halothane depresses circulatory system function. Studies of a variety of mammals, including humans, indicate that cardiac output, stroke volume, and arterial blood pressure are less during halothane anesthesia compared to the awake, unmedicated individual. Further decreases in cardiovascular function accompany increasing alveolar doses of halothane (Pavlin and Su 1994; Bergman 1976; Steffey et al. 1974b,c, 1977; Steffey and Howland, 1978a, 1980; Eger et al. 1970; Ingwersen et al. 1988; Grandy et al. 1989). For example, as halothane dose is increased, mean arterial blood pressure decreases because cardiac output decreases. Total peripheral vascular resistance changes very little; thus, generalized peripheral vasodilation is not the primary cause of hypotension. The reduction in cardiac output is caused by a decrease in stroke volume as a result of a direct drug-induced depression in myocardial muscle contractility.

Effects on heart rate vary widely depending on species and associated conditions. Often there is little change in heart rate over a range of clinical anesthetic doses. The rhythm of the heart beat may vary during halothane anesthesia. Especially at light levels of anesthesia spontaneous arrhythmias may appear. There is some evidence that deeper levels of halothane anesthesia decrease this incidence (Purchase 1966; Muir et al. 1959).

Halothane is especially well noted for its likelihood to predispose the heart to premature ventricular extrasystoles in the presence of catecholamines (Purchase 1966). It is the most potent of the contemporary volatile anesthetics in this regard. Increased endogenous release of catecholamines may occur as a result of surgical stimulation and insufficient anesthesia or from an elevation in P_aCO_2 secondary to hypoventilation. Catecholamines (e.g., epinephrine) and other sympathomimetic amines are sometimes injected during anesthesia and surgery to facilitate patient management or reduce localized bleeding. Thus, anesthetic influence on heart beat rhythm is not a trivial matter. Some anesthetic adjuvant drugs may increase (e.g., xylazine, thiopental, and thiamylal; Tranquilli et al. 1986; Bednarski et al. 1985), and others may decrease (e.g., acepromazine, lidocaine; Muir et al. 1975; Horrigan et al. 1978), the arrhythmogenic dose of epinephrine during halothane anesthesia.

The baroreceptor reflex is a short-term central mechanism to aid in arterial blood pressure homeostasis. Halothane depresses the sensitivity of the baroreceptor reflex (Pavlin and Su 1994).

The cardiovascular effects of halothane change with duration of anesthesia. A time-related increase in arterial blood pressure, stroke volume, and cardiac output has been a common finding in studies of dogs (Steffey et al. 1987b), horses (Dunlop et al. 1987; Steffey et al. 1990a,b, 1993a, 1987d), and humans (Price et al. 1970; Bahlman et al. 1972).

RESPIRATORY SYSTEM. Halothane depresses respiration in a dose-related manner. As a result, the P_aCO_2 increases and there is less efficiency in oxygenating arterial blood and perhaps hypoxemia (Steffey et al. 1977, 1975, 1974c; Steffey and Howland 1978a, 1979a; Grandy et al. 1989). The volume of expired minute ventilation decreases initially as a result of a decrease in tidal volume; respiratory frequency also tends to decrease from awake conditions but the extent is species and condition variable. As anesthetic depth is increased, breathing rate also decreases. In otherwise unmedicated healthy dogs and horses the alveolar halothane concentration that is associated with complete respiratory arrest is 2.9 MAC (Regan and Eger 1967) and 2.6 MAC (Steffey et al. 1977) respectively.

Because halothane has bronchodilator action (Klide and Aviado 1967; Colgan 1965), it has been long considered the anesthetic agent of choice for patients with either a history of asthma or upon anticipated or real bronchospasm during induction or maintenance of anesthesia (Pavlin and Su 1994).

LIVER. Hepatic blood flow is decreased during halothane anesthesia, mostly as a passive consequence of reduced cardiac output and decreased liver perfusion pressure. The reduced blood flow per se, unless extreme, is not usually of a magnitude to result in clinical consequences.

Hepatic dysfunction that sometimes occurs following inhalation anesthesia is most often associated with halothane. The etiology is unknown but the syndrome is likely actually multiple entities (Baden and Rice 1994; Pohl and Gillette 1982). One entity is a mild transient form of hepatic dysfunction that is associated with all of the inhaled (or other) anesthetics and may result from hepatocyte hypoxia (perhaps as a result of reduced tissue oxygen delivery) (Harper et al. 1982a,b; Shingu et al. 1982a,b; Ross and Daggy 1981). Another entity, "halothane hepatitis," is rarer but far more severe and often fatal. The most frequently invoked theories regarding its etiology include the metabolism of halothane to a (hepatic) reactive metabolite (Plummer et al. 1982) and the occurrence of an immune-mediated hypersensitivity (allergic) reaction, a process that is more directly hepatocellularly damaging. The immunological basis for halothane hepatitis has been extensively reviewed (Pohl et al. 1988, 1989; Hubbard et al. 1988).

Laboratory and clinical studies of some clinically important veterinary species (e.g., horses and ponies) indicate there are alterations in hepatic function and cellular integrity associated with halothane anesthesia (Engelking et al. 1984; Gopinath and Ford 1976; Gopinath et al. 1970; Joyce et al. 1983; Steffey et al. 1993c).

KIDNEY. Halothane is not known to have a direct nephrotoxic effect. However, diminution of renal function may occur secondary to an anesthetic reduction in renal blood flow and glomerular filtration rate. The effects reverse rapidly after anesthesia is discontinued (Steffey et al. 1980, 1991, 1993c; Stover et al. 1988).

SKELETAL MUSCLE. Halothane causes some relaxation of skeletal muscle via its action on the CNS. It also increases the magnitude and duration of muscle relaxation induced by nondepolarizing neuromuscular blocking drugs (e.g., pancuronium).

Rarely, induction of anesthesia triggers a rapidly developing hypermetabolic reaction in the skeletal muscle of susceptible individuals. The syndrome was originally described as associated with halothane, but other inhaled anesthetics have also since been implicated. The resultant syndrome of malignant hyperthermia is characterized by muscle rigidity, a rapid rise in body temperature, large consumption of oxygen, and consequent production of CO_2. Death rapidly ensues in most cases unless very aggressive therapy is instituted. Dantrolene is currently the drug of choice for specific therapy.

It is most commonly reported in susceptible swine (Landrace, Pietrain, and Poland China) and human patients and is caused by an acute loss of intracellular control of calcium. The subject has been reviewed by Gronert and Antognini (1994).

Undoubtedly malignant hyperthermia has been wrongfully diagnosed in the past as a cause for hyperthermia in veterinary patients when a more detailed investigation would have revealed other causes.

ISOFLURANE. *Isoflurane*, USP (Forane, Aerrane), is a halogenated methyl ethyl ether. Isoflurane and enflurane are structural isomers. Both compounds contain the same number of atoms of fluorine, chlorine, carbon, hydrogen, and oxygen.

Isoflurane was first synthesized in 1965, and its widespread clinical use for human patients began in 1981. At least in North America, it is now the most widely used volatile anesthetic agent for human patients. Isoflurane is also in widespread clinical use in veterinary patients. It is probably the most commonly used inhaled agent for dogs, cats, horses, and birds.

BIOTRANSFORMATION. In humans and animals isoflurane resists biodegradation. In humans less than 0.2% of the isoflurane taken up by the body is metabolized (Holaday et al. 1975); this rate of metabolism is far less than for halothane, methoxyflurane, and enflurane (Table 11.6). Both inorganic fluoride and trifluoroacetic acid have been identified as end products of isoflurane metabolism (Baden and Rice 1994). The resistance of isoflurane to metabolism accounts for the very small increase in serum fluoride concentration even after prolonged isoflurane administration (Cousins et al. 1973; Dobkin et al. 1973; Mazze et al. 1974a).

Isoflurane is defluorinated by cow, dog, lamb, and rat hepatic microsomes (Rice and Steffey 1985a). In contrast to adult horses, it is not significantly metabolized by neonatal horses (Rice and Steffey 1985b).

The small quantities of degradation products account for the lack of direct renal or hepatic toxicity. Isoflurane also does not appear to be a mutagen, teratogen, or carcinogen (Eger et al. 1978; Eger 1985a).

CENTRAL NERVOUS SYSTEM. Isoflurane, unlike its isomer enflurane, does not produce seizure activity. Cats given isoflurane display "sharp waves" (isolated spiking) on the EEG. This activity is also seen in cats with halothane, enflurane, and methoxyflurane and may be a species peculiarity (Julien and Kavan 1974; Kavan and Julien 1974; Hodgson et al. 1985a).

Isoflurane has become the agent of choice for critically ill animal patients and birds. The MAC for isoflurane is in the range 1.2–1.7% depending upon the species of focus (Table 11.7).

Isoflurane has anticonvulsant effects (Koblin et al. 1981). Electrical silence is seen on the EEG at 2 MAC (Clark and Rosner 1973).

Most studies in animals have shown that isoflurane causes less cerebral vasodilation than halothane (Drummond et al. 1986; Eger 1985a). Cerebral circulation autoregulation is maintained with isoflurane but is impaired by halothane (Todd and Drummond 1984; Miletich et al. 1976). For these reasons isoflurane is usually preferred over halothane for neurosurgery.

CARDIOVASCULAR SYSTEM. Isoflurane depresses cardiovascular function in a dose-related fashion (Steffey and Howland 1977; Steffey et al. 1977, 1987a; Corbally and Brennan 1990; Berl 1990; Eger 1985a; Ludders et al. 1989). The magnitude of its effect on arterial blood pressure is similar to halothane, although with isoflurane the cause is more related to a decrease in the calculated systemic vascular resistance. Also like halothane it decreases cardiac contractility and stroke volume, resulting in a decrease in cardiac output. However, results of studies in a number of species indicate that isoflurane, especially at light and moderate levels, affects cardiac output less than halothane does. Isoflurane thus affords a wider margin of patient safety.

Heart rate tends to be better maintained during isoflurane and may be increased from awake conditions. It remains relatively constant over a range of alveolar isoflurane doses. Heart rhythm is usually little affected by isoflurane, and the incidence of dysrhythmias after injection of vasoactive substances (including catecholamines) is substantially reduced in comparison to halothane (Bednarski and Majors 1986; Eger 1985a; Joas and Stevens 1971; Johnston et al. 1976; Tucker et al. 1974).

As with halothane, duration of isoflurane anesthesia influences the magnitude of cardiovascular function, at least in some species (Dunlop et al. 1987; Steffey et al. 1987c).

RESPIRATORY SYSTEM. Isoflurane, like halothane, depresses respiration and increases P_aCO_2 (Steffey et al. 1977; Steffey and Howland 1977, 1980; Pavlin and Su 1994; Eger 1985a). The magnitude of depression is dose and time related and is at least equal to or greater than that caused by halothane under similar conditions (Steffey et al. 1977, 1985, 1987c; Pavlin and Su 1994; Eger 1985a; Hodgson et al. 1985a; Fourcade et al. 1971; Cromwell et al. 1971).

In some species, like the horse, during light and moderate levels of anesthesia respiration is characterized by large tidal volume and low breathing rate (Hodgson et al. 1985a,b; Steffey et al. 1977). Respiratory depression accompanying isoflurane anesthesia may be increased in magnitude by concurrent administration of opioids (Ossipou and Gebhart 1984; Steffey et al. 1993b), a common practice in clinical circumstances.

The alveolar concentration that causes apnea is 2.5 MAC for the dog (Steffey and Howland 1977) and 2.3 MAC for the horse (Steffey et al. 1977).

The work of Hirshman in dogs sensitized to ascaris antigen suggests that isoflurane (and enflurane) is as effective in decreasing the constrictive ability of airway smooth muscle as halothane (Hirshman et al. 1982). Thus, isoflurane may serve as an acceptable alternative to halothane in animals with elevated airway resistance (Hirshman et al. 1982; Englesson 1974).

LIVER. Blood flow to the liver is altered less by isoflurane than halothane, so isoflurane might be preferable to halothane in patients at risk for hepatic injury (Gelman et al. 1984a,b; Seyde and Longnecker 1984; Gelman 1987; Yasuda et al. 1991). Results of tests of hepatic function and cellular integrity show only minimal changes following isoflurane anesthesia, and the changes are only transient in nature (Daunt et al. 1992; Steffey et al. 1979; Eger 1985a). Transient hepatic insult has been reported with hypoxemia and halothane but not isoflurane anesthesia (Whitehair et al. 1996).

KIDNEY. As with halothane, renal blood flow and urine volume are depressed with isoflurane. Changes in blood components related to renal function and/or injury are not seen or are small in magnitude and are rapidly reversed following anesthesia (Eger 1985a; Daunt et al. 1992; Steffey et al. 1979).

Isoflurane resists metabolism and the release of F⁻ is small, so direct renal toxicity by this drug is unlikely.

SKELETAL MUSCLE. Isoflurane is more potent than halothane in its ability to enhance the neuromuscular blocking effect of nondepolarizing neuromuscular blocking drugs (Miller et al. 1972; Eger 1985a).

Isoflurane is among the anesthetic drugs reportedly able to trigger malignant hyperthermia (Gronert and Antognini 1994).

Muscle blood flow was better maintained in rats, dogs, and humans anesthetized with isoflurane than with halothane (Seyde and Longnecker 1984; Gelman et al. 1984b; Eger 1985a).

METHOXYFLURANE. *Methoxyflurane,* USP (Metofane, Penthrane), was first synthesized in 1958 and was introduced clinically a few years later. It was a popular inhalation anesthetic for anesthetic management of small companion and laboratory animals throughout most of the 1970s and 1980s. Its use for human patients rapidly declined following discovery of its ability to cause vasopressin-resistant polyuria renal failure (Crandell et al. 1966). Over the past 5–10 years its use in clinical veterinary medicine has also been declining as newer anesthetic agents and anesthetic techniques have appeared. Reliable statistics regarding the frequency of its use in clinical practice are not available, but it is judged by this author to be used less than halothane and isoflurane. Because of its extreme blood solubility, imposing costly delays in manipulating anesthetic dose, it was never widely advocated for use with large domestic species. Its use for avian anesthesia has been replaced by isoflurane. Because less objective information is available for methoxyflurane compared to newer volatile anesthetics and because of its perceived decline in use, information on this drug will be more limited in this edition. See earlier editions of this text for additional information.

BIOTRANSFORMATION. Methoxyflurane undergoes substantial biotransformation; in humans about 50% of the absorbed dose can be recovered as metabolites (Table 11.6) (Holaday et al. 1970). It is the most extensively metabolized of the inhaled anesthetics. The major metabolites are F⁻, dichloroacetic acid, and oxalic acid. Both cytochrome P-450-dependent and noncytochrome mechanisms can be involved in its breakdown. The metabolism is increased following administration of enzyme-inducing drugs such as phenobarbital and diazepam (Baden and Rice 1994; Mazze et al. 1974b; Biermann et al. 1986).

CENTRAL NERVOUS SYSTEM. Methoxyflurane is the most potent of the inhalation anesthetics. The MAC for methoxyflurane for the dog is 0.2–0.3% (Eger et al. 1965; Steffey et al. 1984). Values for some other species are given in Table 11.7.

CARDIOVASCULAR SYSTEM. Arterial blood pressure and cardiac output decrease in a dose-related manner (Steffey et al. 1984; Walker et al. 1962). The magnitude of effect in dogs is at least equal to that found with halothane (Steffey et al. 1984; Dobkin and Fedoruk 1961; Bagwell and Woods 1962). As with halothane, the decrease in cardiac output is a result of a decrease in myocardial contractility (Brown and Crout 1971; Merin and Borgstedt 1971). Heart rate changes little over a range of doses, and as is true with all of the anesthetic ethers, cardiac arrhythmias are rare.

RESPIRATORY SYSTEM. Methoxyflurane is a potent respiratory depressant. The increase in P_aCO_2, as with the other volatile anesthetics, is dose related (Steffey et al. 1984). The dose of methoxyflurane resulting in at least 60 seconds of apnea is 3.4 MAC (Regan and Eger 1967).

LIVER. Methoxyflurane along with other inhalation anesthetics reversibly depresses hepatic performance. Though objective data are limited (Pedersoli 1977a), years of uncomplicated use (in relatively healthy dogs) in veterinary practice support the notion that incidence of damage is not great. However, the possibility of liver injury is apparently present in at least some circumstances (Giesecke et al. 1966).

KIDNEY. Renal blood flow, glomerular filtration rate, and urine volume are reduced, as they are with other volatile anesthetics. In especially humans and certain strains of rats (Fischer 344) (Mazze et al. 1972) resultant products (notably F⁻) from the metabolism of methoxyflurane reliably result in nephrotoxicity that is characterized by an inability to concentrate urine (Crandell et al. 1966; Baden and Rice 1994). In addition to rats and humans, the cow, dog, lamb, and probably horse are able to biodegrade methoxyflurane and release F⁻ (Rice and Steffey 1985a,b). Thus, high serum F⁻ is attainable in species other than man and rat following exposure to methoxyflurane. An increase in serum F⁻ following methoxyflurane anesthesia in dogs has been reported (Pedersoli 1977b; Pedersoli 1977a; Fleming and Pedersoli 1980) but under conditions of study clinical signs of renal failure were not obvious. However, anesthetic adjuvant drugs may increase the likelihood of toxicity to methoxyflurane (Matthews et al. 1990).

ENFLURANE. *Enflurane,* USP (Ethrane), was synthesized in 1963, introduced for clinical trial in human patients in 1963, and released for general clinical human use in 1972. Its introduction was encouraged because of the clinical need for an alternative inhalation anesthetic to halothane for human patients. It was investigated for use with small companion animals and horses but received at best only brief clinical exposure.

It is a chemical isomer of isoflurane (Fig. 11.2).

BIOTRANSFORMATION. About 2–10% (Table 11.6) of the enflurane that is administered to humans is biodegraded in the liver (Chase et al. 1971; Carpenter et al.

1986b), with F⁻ as one of its metabolites. Treatment with drugs that induce hepatic enzymes (e.g., phenobarbital) enhances enflurane metabolism (Baden and Rice 1994). The degree of biotransformation occurring with enflurane is substantially less than that found with methoxyflurane and halothane but more than with isoflurane and the two newest inhalation anesthetics.

CENTRAL NERVOUS SYSTEM. The MAC for enflurane in a variety of animal species averages about 2.2% (Table 11.7).

The occurrence of motor hyperactivity such as twitching of the muscles of the face and extremities at moderate levels of anesthesia was noted early in the use of enflurane in both humans and animals. These signs were accompanied by EEG evidence of seizure patterns (Neigh et al. 1971; Clark and Rosner 1973; Joas et al. 1971; Julien and Kavan 1972; Bassell et al. 1982; Steffey and Howland 1978b; Steffey et al. 1977; Steffey 1978; Klide 1976). Enflurane's epileptogenic nature is unique among the commonly used inhaled anesthetics. Hypocapnia seems to potentiate seizurelike activity during enflurane anesthesia (Neigh et al. 1971). Consequently, hyperventilation is usually avoided in the clinical management of patients.

Other effects by enflurane on the CNS are similar to those for halothane and include cerebrovascular dilation, increased cerebral blood flow, and increased intracranial pressure (Michenfelder and Cucchiara 1974; Drummond and Shapiro 1994).

CARDIOVASCULAR SYSTEM. Enflurane causes dose-related depression in cardiovascular function (Calverley et al. 1978a,b; Skovsted and Price 1972; Steffey and Howland 1978b; Steffey et al. 1977; Klide 1976), and overall its effects are considered more profound than those of halothane and isoflurane (Pavlin and Su 1994). Arterial blood pressure is progressively decreased as dose of enflurane is increased. The magnitude of reduction in blood pressure is at least equal to that caused by halothane. Cardiac output also is decreased in a dose-related manner due to a profound depression in myocardial contractility and in turn a decrease in stroke volume. The magnitude of depression in contractility is at least as severe or more so than that produced by halothane (Iwatsuki et al. 1970; Brown and Crout 1971; Merin et al. 1976).

Heart rate may be increased with enflurane. It is intermediate between halothane and isoflurane in its arrhythmogenic potential in the presence of catecholamines (Johnston et al. 1976).

RESPIRATORY SYSTEM. Enflurane is a potent respiratory depressant. The increase in P_aCO_2 is directly related to anesthetic dose (Klide 1976; Steffey and Howland 1978b; Steffey et al. 1977; Calverley et al. 1978a). Enflurane is about equally effective as halothane in decreasing lung airway resistance (Hirshman and Bergman 1978).

LIVER. As with other volatile anesthetics, liver blood flow is reduced in proportion to anesthetic dose and to changes in cardiac output. Hepatic necrosis has been only rarely reported in human patients following enflurane anesthesia (Lewis et al. 1983; Ona et al. 1980; Van der Reis et al. 1974). The influence of accompanying severe hypoxic conditions may have played a prominent role in at least some of these cases (Baden and Rice 1994; Eger et al. 1986). As with halothane, enflurane should probably be avoided in patients suspected of hepatic dysfunction.

KIDNEY. Enflurane, like halothane, depresses renal function. It causes reductions in renal blood flow, glomerular filtration rate, and urine volume that are equivalent in magnitude to those seen with halothane.

The metabolism of enflurane by the liver to F⁻ is much less than that for methoxyflurane. The amount of F⁻ produced is usually below the toxic threshold level (Cousins et al. 1976), so it is unlikely to cause clinically significant renal dysfunction except in unusual circumstances like prolonged anesthetic conditions (Barr et al. 1974; Mazze et al. 1977).

SKELETAL MUSCLE. Skeletal muscle relaxation occurs with enflurane, and nondepolarizing neuromuscular blocking drugs are more potent in the presence of enflurane (Fogdall and Miller 1975; Lebowitz et al. 1970). Malignant hyperthermia is induced in susceptible individuals by enflurane (Caropreso et al. 1975; Gronert and Antognini 1994).

DESFLURANE. *Desflurane*, USP (Suprane), is the newest inhalation anesthetic released for general clinical use in human patients in North America, United Kingdom, and other parts of Europe. Its actions have been investigated in humans and in a variety of animal species, including dogs, horses, and pigs. Reviews of its actions are in Eger 1993 and 1994.

Desflurane, formally known as I-653, was first synthesized in the 1960s along with similar agents such as enflurane and isoflurane. It was not actively investigated at that time because it was difficult to produce and its greater anesthetic potency compared to other prospects was considered undesirable (Eger 1993).

Desflurane has a high vapor pressure (Table 11.3) and required a newly designed, temperature-controlled, pressurized vaporizer for predictable delivery (Andrews and Johnston 1993). It has a very low solubility (Eger 1987) in blood (Table 11.4), contributing to greater precision of control over the maintenance of anesthesia and a very rapid emergence from anesthesia (Eger 1992).

BIOTRANSFORMATION. Desflurane resists degradation by the body to a greater degree than any of the other volatile anesthetics (Koblin 1992; Koblin et al. 1988); actual amounts of degradation are too small to measure accurately. Results to date do not indicate any toxicity associated with its use in a variety of species. Although the magnitude of breakdown is different, desflurane is expected to be metabolized in a manner similar (parallel) to that for isoflurane (Baden and Rice 1994). Resulting products are free fluoride ions, trifluoroacetic acid, and CO_2 and water (Eger 1993).

CENTRAL NERVOUS SYSTEM. Desflurane is less potent than other contemporary volatile agents (Table 11.7). For example, the MAC for the dog is 7.2%.

Desflurane causes dose-related depression of EEG activity comparable to effects seen with an equipotent dose of isoflurane (Rampil et al. 1988, 1991). Epileptiform EEG activity is not reported.

Desflurane causes dose-dependent decreases in cerebrovascular resistance (vasodilation) and cerebral metabolic rate of oxygen consumption similar to actions by halothane and isoflurane (Lutz et al. 1990). As is the case with isoflurane, desflurane may also result in an increase in brain volume and associated intracranial pressure increase (Young 1992). Although these effects are trivial in animals without intracranial pathology (Lutz et al. 1990, 1991), the agent must be used carefully in patients with decreased intracranial compliance. Desflurane is similar to isoflurane in that cerebrovascular responsiveness to carbon dioxide is maintained (Lutz et al. 1991).

CARDIOVASCULAR SYSTEM. The cardiovascular actions of desflurane are similar to those of isoflurane (Weiskopf et al. 1988, 1989b, 1991; McMurphy and Hodgson 1994; Warltier and Pagel 1992). Like isoflurane and halothane, desflurane decreases mean arterial blood pressure and stroke volume in dose-related fashion. But cardiac output during desflurane, as with isoflurane, is better maintained compared to conditions during halothane anesthesia. Heart rate is usually higher and peripheral vascular resistance less with desflurane compared to the other volatile agents (Pagel et al. 1991b). Myocardial contractility is depressed (Pagel et al. 1991a; Boban et al. 1992). Desflurane does not predispose the heart to ventricular arrhythmias, nor does it sensitize it to arrhythmogenic effects of epinephrine (Moore et al. 1993; Weiskopf et al. 1989a).

RESPIRATORY SYSTEM. Desflurane, like other contemporary volatile anesthetics, causes a dose-related respiratory depression (Lockhart et al. 1991a). Its effects in this regard in humans are most comparable to those of enflurane (i.e., more depressing than isoflurane). Apnea occurs in pigs at alveolar desflurane concentrations between 1.2 and 1.6 MAC, while the apneic threshold in dogs is 2.38 MAC (Warltier and Pagel 1992).

LIVER. Desflurane depresses hepatic blood flow only minimally. In a study of dogs, total hepatic blood flow (portal plus hepatic arterial) was significantly decreased by desflurane only at the two highest anesthetic concentrations (1.75 and 2.0 MAC) (Merin et al. 1991). These actions were not significantly different from isoflurane.

Desflurane is not associated with hepatic toxicity in humans (Jones et al. 1990; Weiskopf et al. 1992), swine (Holmes et al. 1990), or rats (Eger et al. 1987).

KIDNEY. Renal blood flow is not substantially altered by desflurane (Merin et al. 1991). Because desflurane is extremely resistant to degradation, it is not expected to possess, and has not to date shown, nephrotoxic potential (Baden and Rice 1994; Jones et al. 1990; Weiskopf et al. 1992).

SKELETAL MUSCLE. Desflurane, like isoflurane and enflurane, causes muscle relaxation and enhances the action of neuromuscular blocking drugs (Caldwell et al. 1991). Desflurane is also a trigger of malignant hyperthermia in susceptible swine (Wedel et al. 1991).

SEVOFLURANE. *Sevoflurane* (Ultane) was synthesized in the early 1970s, and its characteristics were first described in 1975 (Wallin et al. 1975). It has been approved for use in human patients in Japan for nearly two decades. It is now available in North America for general use in human patients.

Its physical characteristics were noted earlier in this chapter. However, it is important to point out here again that unlike other contemporary inhalation anesthetics sevoflurane is degraded in the presence of soda lime and Baralyme, commonly used CO_2 absorbents in anesthetic delivery circuits (Wallin et al. 1975; Liu et al. 1991; Strum et al. 1987; Frink et al. 1992a). Sevoflurane degrades to $CH_2F\text{–}O\text{–}C{=}CF_2$ (CF_3) (known as Compound A) that is lethal in 50% of animals (LD_{50}) at a concentration of 400 ppm (Morio et al. 1992). Mazze (1992) has discussed concerns of levels of Compound A in human patients.

The in vitro rate of defluorination of sevoflurane is about the same as for methoxyflurane (Cook et al. 1975a,b). In vivo, however, the serum F^- concentration associated with sevoflurane is much less than with methoxyflurane (Cook et al. 1975a; Holaday and Smith 1981; Baden and Rice 1994; Martis et al. 1981). Likely this difference is related to sevoflurane's reduced tissue solubility. Sevoflurane defluorination is increased by prior induction of microsomal enzymes with drugs such as phenobarbital (Cook et al. 1975b; Baden and Rice 1994).

Like desflurane and other commonly used inhalation anesthetics, sevoflurane decreases cerebral vascular resistance and cerebral metabolic rate, increases intracranial pressure in a dose-related manner (Drummond and Shapiro 1994; Manohar 1986; Scheller et al. 1988), and does not cause EEG or gross motor evidence of seizure activity in dogs (Wallin et al. 1975; Scheller et al. 1990).

Except for causing a higher heart rate, sevoflurane's actions on the circulatory and respiratory systems are qualitatively and quantitatively similar to those of isoflurane (Eger 1994). Sevoflurane does not increase the arrhythmogenicity of the heart (Wallin et al. 1975), and the arrhythmogenic dose of epinephrine in dogs anesthetized with sevoflurane is similar to that during isoflurane anesthesia (Hayashi et al. 1988).

Current information suggests that sevoflurane or its degradation products do not produce hepatic or renal injury. However, caution is warranted since the biodegradation of sevoflurane to F^- occurs and degradation by soda lime or Baralyme produces another renal toxic agent, Compound A. The concentration threshold for renal toxicity in rats can be reached in clinical practice (Eger 1993, 1994). Indeed, recognition of possible renal damage from Compound A led to the present package labeling for sevoflurane that warns physicians against its use for human patients at fresh gas flow rates (from the anesthetic delivery apparatus) of less than 2 L/min. Mazze and Jamison (1995) recommend that sevoflurane not be used in patients with impaired renal function.

Sevoflurane enhances the action of neuromuscular blocking drugs and can trigger malignant hyperthermia in susceptible animals (Gronert and Antognini 1994; Schulman et al. 1981).

DIETHYL ETHER. *Ether,* USP (diethyl ether; C_2H_5–O–C_2H_5), is a colorless volatile liquid with a characteristic odor. It has a vapor pressure of about 425 mm Hg (at 20° C) and boils at 35° C. Because of its ease of vaporization and wide margin of safety it can be used with simple vaporizers positioned within the patient breathing circuit.

Its blood/gas PC at 37° C is 12, very near that for methoxyflurane (Eger 1974). Its vapor is highly flammable and forms an explosive mixture with air. This, along with the introduction of halothane and methoxyflurane and the introduction of more electronic tools into the operating room, in large part accounted for its rapid decline from widespread clinical use in North America in the 1960s.

Ether is biodegraded in the body to CO_2 and nonvolatile urinary products. It is presumed that the ether linkage is cleaved by hepatic microsomal enzymes (mixed-function oxidase system), producing two-carbon by-products such as ethanol and acetic acid, which then enter the general metabolic pool and are further oxidized to CO_2 (Van Dyke et al. 1964; Green and Cohen 1971; Cohen 1971). From a metabolic viewpoint, ether is a very safe agent because it degrades into nontoxic products (Green and Cohen 1971). Most of the ether unaltered is eliminated via the expired air.

Ether is an excellent anesthetic and causes dose-related generalized CNS depression. The MAC for ether in dogs is 3.04% (Eger et al. 1965). The MACs for other species are summarized elsewhere (Eger 1974).

Ether at anesthetic concentrations is an irritant to the mucosa of the respiratory tree and as a result increases the amount of respiratory tract secretions. In humans and dogs ventilation is not severely depressed until deep levels of ether anesthesia are produced (Larson et al. 1969; Muallem et al. 1969).

In sympathetically denervated animals, ether depressed myocardial contractility (Brewster et al. 1953; Brown and Crout 1971). In the animal with intact sympathetic nervous system responses, diethyl ether is known to provide universally stable hemodynamic conditions. Cardiac output and heart rate usually increase, and arterial blood pressure remains stable. An increase in sympathetic nervous activity is the mechanism that compensates for the direct depressant action of ether (Jones et al. 1962; Price 1961; Skovsted and Price 1970; Eger et al. 1971).

Emesis is a common complication of low-dose ether and frequently occurs during anesthetic recovery in otherwise unmedicated dogs. Ether also provides profound skeletal muscle relaxation.

THE GASEOUS ANESTHETIC: NITROUS OXIDE. The pharmacology of N_2O and its scope in the clinical practice of anesthesiology (human and animal patients) have been reviewed by Eger, and readers are advised to consult his text as the next step for information beyond the brief summary given here (Eger 1985b).

Nitrous oxide, USP (N_2O), is a colorless, nonirritant, slightly sweet-smelling, nonflammable gas. Nitrous oxide is commercially available as a gas stored in steel cylinders at a pressure of about 50 atmospheres. Since its introduction into clinical practice more than 150 years ago, its use has formed the basis for more general anesthetic techniques of human patients than any other single inhalation agent. Its widespread use resulted from many desirable properties, including low blood solubility (Table 11.4), limited cardiovascular and respiratory system depression, and minimal toxicity (Eger 1985b). Its use in the anesthetic management of animals became a natural extension of its use for humans.

An overview of uptake and distribution (pharmacokinetics) of inhalation anesthetics including brief insight into some relatively unique ways the physical properties of N_2O influence its movement into, within, and from the body was given above and because of space limitations will not be further addressed here. Readers are referred to the works of Eger (Eger 1974, 1985b) for more information on such clinically important subjects as "the second gas effect," "diffusion hypoxia," and movement of N_2O into closed gas spaces.

BIOTRANSFORMATION. Nitrous oxide is metabolized (reductive pathway) by intestinal anaerobic bacteria to molecular nitrogen (N_2) and free radicals (Hong et al. 1980a,b). Unlike other inhalation anesthetics, N_2O is not believed to be directly metabolized by animal tissues.

CENTRAL NERVOUS SYSTEM. Nitrous oxide is not a potent anesthetic (Table 11.7) and under ambient conditions will not anesthetize a fit, healthy individual. Consequently, to get important benefits of N_2O it is necessary to use it in high inspired concentrations but at the same time remembering that as the concentration of N_2O is increased there is a change in the proportion and partial pressure of the various other constituents of the inspired breath, notably O_2. Consequently, to avoid hypoxemia, 75% of the inspired breath is the highest concentration that can be safely administered (at sea level to healthy individuals, less at altitude or in the face of, especially, cardiopulmonary disease). The potency of N_2O in animals important to clinical veterinary medicine is only about one-half the anesthetic potency of that found in humans. Thus, the value of N_2O in veterinary clinical practice is further compromised. When used it serves as an anesthetic adjuvant; that is, it is used in conjunction with an injectable and/or another inhalation anesthetic. Since its depression of other vital organs such as the heart, lungs, kidneys, etc., is small, its purpose in this case is to reduce the amount of the primary, more potent inhaled or injectable anesthetic drug for anesthesia to lessen overall harmful effects on vital organ function.

The effects of N_2O on the EEG are similar to those produced by the volatile anesthetics. At low subanesthetic levels (about 30%, inspired), N_2O increases EEG frequency and lowers voltage, and at higher subanesthetic concentrations (e.g., 60%), N_2O increases voltage. Adding N_2O to a light level of anesthesia produced by other drugs tends to increase voltage and decrease frequency (Frost 1985).

At subanesthetic doses N_2O causes an increase in cerebral blood flow and intracranial pressure. The magnitude of change seems to depend upon whether it is administered alone or in conjunction with other anesthetics. Dramatic increases in intracranial pressure occur in animals when N_2O is used alone (Theye and Michenfelder 1968; Pelligrino et al. 1984; Drummond and Shapiro 1994).

CARDIOVASCULAR AND RESPIRATORY SYSTEMS. Under ambient conditions the effects of N_2O on the cardiovascular and respiratory function (other than reducing the inspired O_2 concentration) are small compared to those of the other inhalation anesthetics. Nitrous oxide is a direct myocardial depressant. However, it also causes sympathetic nervous system stimulation and the release of catecholamines. The sympathetic stimulation, coupled with the mild, direct depressant properties of N_2O, results in comparatively little cardiovascular depression (Eisele 1985; Steffey et al. 1974a,b, 1975; Steffey and Howland 1978c; Dolan et al. 1974; Pavlin and Su 1994; Eger 1985b). This end result is one of the distinguishing factors of N_2O relative to the other inhalation anesthetics.

In some circumstances N_2O may contribute to an increased incidence of cardiac arrhythmias (Liu et al. 1982; Lampe et al. 1990a). There is some evidence to suggest that its use contributes to an increased incidence of myocardial ischemia in some circumstances (Philbin et al. 1985; Leone et al. 1988; Nathan 1988; Diedericks et al. 1993).

LIVER AND KIDNEY. Nitrous oxide has little or no effect on liver or kidney function in patients exposed under most clinical circumstances (Brodsky 1985; Lampe et al. 1990b,c). Nitrous oxide interferes with several vitamin B_{12} dependent reactions. The result is an irreversible inactivation of the enzyme methionine synthase that in turn results in a reduced amount of thymidine, an essential DNA base. The subsequent interference with DNA synthesis prevents production of both leukocytes and red blood cells by bone marrow. Similarly, exposure to N_2O can produce a polyneuropathy ("nitrous oxide neuropathy") that is indistinguishable from that associated with pernicious anemia, that is, subacute degeneration of the spinal cord (Baden and Rice 1994; Brodsky 1985). The bone marrow changes would be expected to be seen only in the sickest of patients and after about 10 hours or more of N_2O anesthesia (O'Sullivan et al. 1981). The neurologic disease is most commonly associated with rare, long-term exposure in a grossly contaminated work environment or with chronic abuse of N_2O (a potential consideration in the management of the veterinary practice) (Layzer et al. 1978; Layzer 1978; Baden and Rice 1994; Brodsky 1985). Both forms are described in humans and animals.

SKELETAL MUSCLE. Nitrous oxide is at best only a weak trigger to the development of malignant hyperthermia in susceptible subjects (Gronert and Antognini 1994).

TRACE CONCENTRATIONS OF INHALATION ANESTHETICS: OCCUPATIONAL EXPOSURE.

In 1968, Bruce and coworkers (Bruce et al. 1968) published a retrospective study of the causes of death among anesthesiologists over a 20-year period. Their work revealed a trend toward higher than normal incidences of death from reticuloendothelial and lymphoid malignancies. The possibility that chronic exposure to low levels of waste inhalation anesthetic agents constitutes a health hazard to medical personnel attracted worldwide interest among health workers (Cohen et al. 1971, 1975; Linde and Bruce 1969; Whitcher et al. 1971; Millard and Corbett 1974; Manley and McDonell 1980b; Milligan et al. 1980; Dreesen et al. 1981; Manley et al. 1982). Of particular concern are reports that inhalation anesthetics are potential mutagens, carcinogens, and/or teratogens and that fetal death, spontaneous abortion, birth defects, or cancer in exposed workers might result (Ad Hoc Committee on the Effect of Trace Anesthetics on the Health of Operating Room Personnel 1974; Cohen et al. 1971). To date, "the overwhelming conclusion from both animal and human studies is that there is no carcinogenic risk either from working in the operating or dental suite or from exposure to anesthetics" (Baden and Rice 1994). "[T]he overwhelming evidence from in vitro tests indicates that all currently used and most previously used anesthetics are not mutagens . . . [however,] two recent (1990 and 1992) studies have shown cytogenic damage in operating room personnel exposed to waste anesthetic gases (Natarajan and Santhiya 1990; Sardas et al. 1992)" (Baden and Rice 1994). Data to date regarding human reproduction effect remain equivocal; a firm cause-and-effect relationship between chronic exposure to trace levels of anesthetics and human health problems does not exist. Nevertheless, interest in this topic remains high and is fueled by, for example, a study in which reduced fertility was reported among dental assistants exposed to high levels of nitrous oxide

(Rowland et al. 1992). For more in-depth review of potential hazards to health care providers, readers are referred to Baden and Rice's (1994) updated chapter in Miller's *Anesthesia* (pp. 172–179).

The risk of long-term exposure to trace concentrations of inhalation anesthetics for those in operating-room conditions seems minimal. However, "even if anesthetics have low potential for causing long-term toxicity, exposure of a large population may represent a considerable public health hazard . . . surgeons, dental personnel, and *veterinarians and their technical assistants* have a variable but sometimes heavy exposure to [inhalation] anesthetics. The total number of occupationally exposed or potentially exposed persons in the United States each year is about 225,000 (National Institute for Occupational Safety and Health (NIOSH) 1977)" (Baden and Rice 1994, emphasis added). Accordingly, current knowledge is suggestive enough to cause concern and to encourage practices to reduce the contamination by inhalation anesthetics of operating-room personnel. More information on this subject is available in anesthesiology texts such as Miller's *Anesthesia* and elsewhere (Lecky 1977, 1980; Ad Hoc Committee on Effects of Trace Anesthetic Agents on Health of Operating Room Personnel 1983; Manley and McDonell 1980a; Dorsch and Dorsch 1984).

    Secobarbital Sodium
    Hexobarbital Sodium
Propofol
Etomidate
Chloral Hydrate
Chloral Hydrate and Magnesium Sulfate
Guaifenesin
Althesin
Dissociative Anesthetics
    Phencyclidine Hydrochloride
    Ketamine Hydrochloride
    Tiletamine Hydrochloride
Miscellaneous Agents
    Chloralose
    Urethane
    Propanidid
    Metomidate

Stages of anesthesia for central nervous system (CNS) depressants are similar in a patient whether anesthetic is injected intravenously or administered by inhalation. However, it is possible to proceed more rapidly through induction with IV anesthetics than with almost all of the inhalation anesthetics. Clinically, a rapid course of induction is desirable to avoid excitement and struggling.

Anesthetics administered intravenously appear to conform to the same laws of tissue distribution and the same theories of activity as discussed for other anesthetics. There is no anesthetic agent that produces ideal anesthesia under all circumstances. It is desirable to know advantages and disadvantages of different methods and drugs producing general anesthesia to select the kind most suited to a particular clinical condition.

INDICATIONS FOR INJECTABLE ANESTHESIA. There are many situations where injectable anesthesia has distinct advantages over inhalation anesthesia. Induction of general anesthesia and intubation are often accomplished most efficaciously by the IV injection of a short-acting anesthetic or, in the case of animals that are difficult to restrain, the intramuscular (IM) injection of an anesthetic agent. Some minor procedures require only a short time, and injectable anesthesia provides a safe and efficient means of providing short-duration anesthesia. The increased use of endoscopic upper airway examination has also increased the use of injectable anesthesia. The use of injectable anesthesia allows easy visualization of the larynx and proximal trachea as well as endoscopic examination of the distal airways without the difficulties of administering inhalation anesthesia concurrently. Large-animal surgical procedures (especially equine) are often done using injectable anesthesia since the equipment needed for inhalation anesthesia is not readily transportable. The capture and immobilization of wild animals rely almost exclusively on injectable anesthetics or related compounds. Finally, in situations where economy is the primary concern, the use of injectable anesthesia is attractive since there is no need to invest in the equipment required to administer inhalation anesthesia.

DISADVANTAGES OF INJECTABLE ANESTHESIA. Traditionally the depth, or level, of anesthesia has been thought to be less readily controlled with drugs injected intravenously or parenterally than with inhalation anesthetic agents. However, some of the agents currently available have such short durations of action that depth of anesthesia can be readily adjusted by changing the administration rate.

A major portion of inhalant anesthetics is rapidly eliminated unaltered in exhaled air after administration ceases, whereas an injectable anesthetic drug ceases to act only after it is metabolized and/or excreted. However, use of ultrashort-acting barbiturates and other even shorter acting agents, most notably propofol, have provided better control of IV anesthesia. These have made possible safe and satisfactory anesthesia without the use of inhalation agents. The concurrent use of other drugs such as opiates and tranquilizers improves the analgesia and muscle relaxation.

Many injectable anesthetic agents as well as agents commonly used concurrently with them are classified as controlled substances under the 1970 Controlled

Substances Act. This places restrictions on the purchase, storage, and use of these drugs.

PROPERTIES OF AN IDEAL INJECTABLE ANESTHETIC DRUG. There is no ideal injectable (or inhalation) anesthetic drug available at this time. One can, however, hypothesize what properties such a drug would have. These can be divided into physiological and pharmacological properties.

Ideal Physiological Properties. The ideal injectable anesthetic agent should provide physiological homeostasis. This means there should be no life-threatening changes in cardiovascular and respiratory function. There should be analgesia that is adequate for the procedure to be performed. Some degree of muscle relaxation should be produced. The amount of muscle relaxation needed certainly varies with the procedure. Finally, an injectable anesthetic needs to produce unconsciousness. Since pain is a psychological perception, anything that produces unconsciousness will provide some degree of analgesia by depressing the activity of the higher centers of the brain (Kitchell 1983).

Ideal Pharmacological Properties. An ideal injectable anesthetic should have a wide margin of safety in a variety of species. It should have a short duration of action with minimal cumulative effects so the duration of anesthesia could be easily controlled. The drug should be readily metabolized and/or excreted: ideally by more than one route. And finally a specific and complete reversal agent should be available.

THE BARBITURATES. Barbital sodium and phenobarbital were the first of the barbituric acid derivatives introduced into medicine. When used to produce anesthesia, the major limitation of the earlier barbiturates was their long period of action. In 1924 Somnifene was used intravenously to produce general anesthesia. Dial was introduced during the same year. Pentobarbital was introduced in 1926 by Page and Coryllos for animal experimental use; by 1930, it was used in clinical veterinary medicine. During 1928 amobarbital sodium was employed in animals.

In 1933 hexobarbital sodium was introduced and recognized as a marked advancement in IV anesthesia because of a very rapid hypnotic action of brief duration. In 1934 thiopental sodium was introduced and appeared to possess certain advantages over hexobarbital. In 1946 and 1948 respectively, new ultrashort-acting barbituric acid derivatives called thialbarbital sodium and thiamylal sodium were introduced into veterinary medicine.

There are many other barbituric acid derivatives (e.g., aprobarbital, butabarbital, mephobarbital, metharbital, probarbital, talbutal). These, however, are infrequently or seldom used in veterinary medicine; several of the most widely used barbituric acid derivatives are listed in Table 12.1, with generalizations regarding official status, duration of action, and chemical structure.

Intermediate- and long-acting barbiturates should be restricted to sedative or anticonvulsant use. Their long action precludes using them for general anesthetic purposes.

Chemistry. The barbiturates are bitter-tasting white powders except for those containing sulfur. These may have a yellowish tint. Barbiturates are hygroscopic and will decompose on exposure to air, heat, and light. They should be stored in dark bottles, sealed ampules, or colored capsules. Solutions of barbiturates decompose rapidly unless stabilized. Boiling of aqueous solutions quickly decomposes most barbiturates. Certain thiobarbiturates are relatively unsta-

TABLE 12.1—Major barbiturates used in veterinary medicine

	Official names and synonyms	Approximate duration of action	Radicals attached to carbon 5	
			R_1	R_2
←decreased-Duration-increased→	Phenobarbital Sodium (soluble phenobarbital, soluble phenobarbitone, luminal sodium), USP	Long	Ethyl	Phenyl
	Barbital Sodium (soluble barbital, soluble barbitone, veronal sodium), NF	Long	Ethyl	Ethyl
	Amobarbital Sodium (amytal sodium), USP	Intermediate	Ethyl	Isoamyl
	Pentobarbital Sodium (nembutal sodium), USP	Short	Ethyl	1-Methyl butyl
	Secobarbital Sodium (seconal sodium), USP	Short	Allyl	1-Methyl butyl
	Thiopental Sodium* (pentothal sodium), USP	Ultrashort	Ethyl	1-Methyl butyl
	Thiamylal Sodium* (surital sodium), USP	Ultrashort	Allyl	1-Methyl butyl
	Thialbarbital Sodium* (kemithal sodium), INN	Ultrashort	Allyl	Cyclohexenyl
	Methohexital Sodium† (Brevane), USP	Ultrashort	Allyl	1-Methyl-2-pentynyl

*Sulfur replaces oxygen on carbon 2.

†Methyl group replaces hydrogen on nitrogen 1.

ble; solutions of these may be entirely decomposed in 36 hours at room temperature but will last longer if refrigerated.

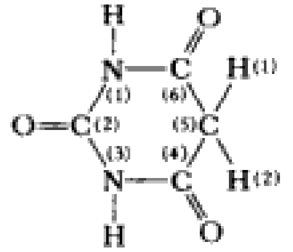
Barbiturates are derived from the nondepressant barbituric acid or malonylurea, which contains a pyrimidine nucleus. When the hydrogens on carbon 5 are substituted with an appropriate alkyl or aryl group, depressant activity on the CNS is possessed by the compound. A few barbituric acid derivatives contain a sulfur atom attached to carbon 2 in substitution for the oxygen (see Fig. 12.1).

Barbituric acid and its carbon 5 substituted derivatives are sparingly soluble in water. Aqueous solutions are weakly acid and will combine with sodium or other fixed alkalis to form water-soluble salts. The sodium atom joins the oxygen atom attached to carbon 2. These salts hydrolyze in water to form alkaline solutions with a pH usually between 9 and 10.

Conversion of barbituric acid derivatives into water-soluble salts made possible the IV injection of barbiturates that has been so widely and satisfactorily practiced in veterinary medicine.

Several hundred barbituric acid derivatives have been synthesized, but only a few have survived the rigors of clinical trial. From pharmacologic study of these compounds, certain relationships of chemical structure and pharmacologic response have become apparent, so certain generalities are justified:

1. To be hypnotically effective, both hydrogen atoms on carbon 5 must be replaced by an alkyl or aryl group.
2. To obtain optimal therapeutic results, the substituting radicals on carbon 5 should contain a minimum of 4 and a maximum of 9 carbons; addition of more leads to convulsant activity.
3. Unsaturated carbon chains are more readily oxidized and hence are short acting.
4. Short chains are more stable and hence are long acting.
5. Long chains are easily oxidized and are short acting.
6. Branched chains tend to be shorter in action than straight chains.
7. Only one aryl radical should be attached to carbon 5.



Barbituric Acid (malonylurea)

FIG. 12.1

8. Replacement of the oxygen atom on carbon 2 by a sulfur atom increases potency and instability and shortens duration of action of the compound.
9. Attachment of an alkyl group to one of the N atoms (position 1 or 3) increases anesthetic potency and tends to stimulate the CNS. Substitution in both N atoms produces a convulsant.
10. Replacement of the oxygen on carbon 2 by an HN= group destroys the hypnotic activity of the molecule.

Central Nervous System. The major action of barbiturates is to depress the CNS. This effect is the reason for the extensive use of barbiturates in medicine. Effects upon other systems become important as toxic limitations to use of the drug are approached.

Each of the many barbiturates depresses the CNS. Clinically they differ in respect to effective dosage, time required for initial effect, duration of action, and method of administration. The degree of depression may vary from mild sedation and hypnosis to surgical anesthesia.

Barbiturates both enhance and mimic the action of the neurotransmitter γ-aminobutyric acid (GABA), the principal inhibitory neurotransmitter in the CNS (Olsen 1988). Barbiturates depress the cortex of the brain and probably the thalamus. They depress motor areas of the brain and thus can be used to control convulsive seizures. They also depress sensory areas and induce anesthesia. Relatively large dosages of barbiturates are necessary to deaden the physiological response to noxious stimuli. Pentobarbital plasma concentrations necessary to abolish the response to noxious stimuli in the dog is 23 ± 2.9 μg/mL (Frederiksen et al. 1983).

Numerous investigations have shown a decrease in oxygen uptake by the brain following barbiturate administration. Utilization of oxygen by the cortical areas of the brain is more depressed than by other regions of the CNS. In clinical concentrations, barbiturates are the most potent known depressants of cerebral oxygen consumption (Steen and Michenfelder 1979). As much as a 55% decrease in oxygen consumption may occur.

Barbiturate anesthetics, but not anticonvulsants, abolish the spontaneous activity of cultured spinal cord neurons; the anesthetics directly increase membrane conductance, an effect that is suppressed by GABA antagonists such as picrotoxin and penicillin (Macdonald and Barker 1978). Pentobarbital is GABA-mimetic; i.e., it interacts with GABA receptors to produce an increase in neuronal chloride conductance (Saunders and Ho 1990; Davies et al. 1998). A major action of GABA, an inhibitory neurotransmitter substance, is to increase chloride permeability in postsynaptic neurons (Enna 1981). The sedative and anesthetic properties of the barbiturates are a result of their interaction with the GABA receptor complex. When barbiturates bind to the barbiturate receptor portion of the GABA receptor complex, the rate of dissociation of GABA from its receptor is decreased and increased chloride conductance is maintained. This results in membrane hyperpolarization and reduced neuronal excitability. As the barbiturate concentration increases, barbiturates can directly activate chloride channels even without GABA present. The GABA-dependent increase in chloride conductance may be the mechanism for the sedative-hypnotic effects of the barbiturates while the GABA- independent increases result in "anesthesia" (Fragen and Avram 1994). It is becoming more apparent that there is a multiplicity of GABA, barbiturate, and benzodiazepine receptors that are associated or linked together in many ways.

Transmission of nerve impulses at synaptic as well as at neuroeffector junctions is normally decreased by barbiturates; blocking effects of decamethonium and *d*-tubocurarine upon skeletal muscle are increased. These effects occur because barbiturates decrease sensitivity of polysynaptic junctions to the depolarizing action of acetylcholine.

It has been demonstrated in animals, particularly cats, that barbiturates raise the threshold of spinal reflexes. Lowering of the threshold by strychnine can be overcome by barbiturates, even to the practical elimination of crossed reflexes. Barbiturates are used clinically with considerable success in treatment of strychnine poisoning and other convulsants.

Numerous investigators have directed their work toward the effect of barbiturates upon the reticular activating system of the CNS. This system is particularly sensitive to barbiturates (Harvey 1975). Animals are unable to be aroused or to maintain the wakeful state following administration of hypnotic to anesthetic dose levels of barbiturates.

Respiratory Center. With the exception of the cat, therapeutic doses of barbiturates depress respiration slightly, but no more than would be expected from the general sedation produced by the drug. In the cat the marked susceptibility of respiratory function following barbiturate administration, especially its marked blocking effect upon the reticular formation, may explain why this animal reacts adversely to barbiturates. The reticular formation of the cat apparently feeds signals or impulses into the medullary control centers governing respiration. In contrast to a single major mechanism in most other species, respiratory activity appears to be governed at two levels within the CNS.

In many animals, subanesthetic doses of barbiturates accelerate respiration rate (Borison 1978). Conversely, large doses are markedly depressant to the respiratory center in the medulla. Doses of barbiturates that induce deep surgical anesthesia severely depress frequency as well as tidal volume of respiration, resulting in a dangerous hypoxia and respiratory acidosis.

IV injection of a barbiturate produces a more severe depression of respiration than that following oral administration, probably as a result of production of a higher momentary concentration of drug effective upon the center. The blood concentration inhibiting the respiratory center is considerably less than that arresting the heart. Therefore, when respiratory arrest occurs during barbiturate anesthesia, attention should be devoted first to reestablishing respiration, since the heart continues to function for a brief period. According to Chenoweth and Van Dyke (1969), more animals are lost from failure to maintain an adequate airway than from any other single difficulty in anesthesia. In most species, insertion of an endotracheal tube can be accomplished so that oxygen and artificial ventilation may be given when depression of respiration results from an anesthetic overdose. Pentobarbital at a dose of approximately four times that producing respiratory arrest may be administered before cardiac arrest occurs in the artificially ventilated animal.

Cardiovascular System. Pentobarbital is probably the most widely used IV anesthetic by biomedical research laboratories in a dose of 25–30 mg/kg in the dog (Frederiksen et al. 1983). Although there is universal agreement that the anesthetic induces tachycardia (originally thought to be caused by its vagolytic activity in the above dose), reports of its effects on arterial pressure and cardiac output are divergent. An excellent study of pentobarbital anesthesia upon various hemodynamic parameters has been conducted in the dog by Manders and Vatner (1976); effects upon mean arterial pressure, systolic arterial pressure, cardiac output, total peripheral resistance, and heart rate are summarized in Fig. 12.2 for intact and denervated (bilateral sectioned carotid sinus and aortic nerves) dogs. Mean arterial pressure drops from a control of 91 ± 2 to 85 ± 3 mm Hg at 2.5 minutes; it returns to control at 7.5–10 minutes and then falls slightly below at 15–25 minutes. Systolic arterial pressure is significantly depressed for the entire measurement period. Cardiac output rises from 2.20 ± 0.16 to 2.73 ± 0.24 L/min at 2.5 minutes, then gradually declines. However, it is significantly reduced below the control only at 25–30 minutes. The total peripheral resistance drops significantly below control at 2.5 minutes, rises above the control at 15 minutes, and remains significantly elevated. Stroke volume falls from 33 ± 3.0 to 18 ± 2.8 mL ($P < 0.01$) and remains significantly depressed. Heart rate rises from 80 ± 3 to 160 ± 4 beats/min at 2.5 minutes, then drops gradually to 109 ± 5 beats/min at 30 minutes. Myocardial contractility in the dog falls significantly following pentobarbital anesthesia, as reflected by 30–40% decreases in myocardial force ($\Delta P/\Delta t$), myocardial velocity, and shortening velocity (Manders and Vatner 1976).

Following bilateral sectioning of the carotid sinus and aortic nerves, the role of arterial pressoreceptor reflexes in the dog has been determined during pentobarbital anesthesia (Manders and Vatner 1976). As anticipated, in denervated animals, arterial pressure drops by a significantly greater amount. The most surprising effect of denervation is absence of tachycardia after pentobarbital anesthesia. Inasmuch as heart rate does not remain elevated during anesthesia in denervated dogs, the mechanism for tachycardia appears to

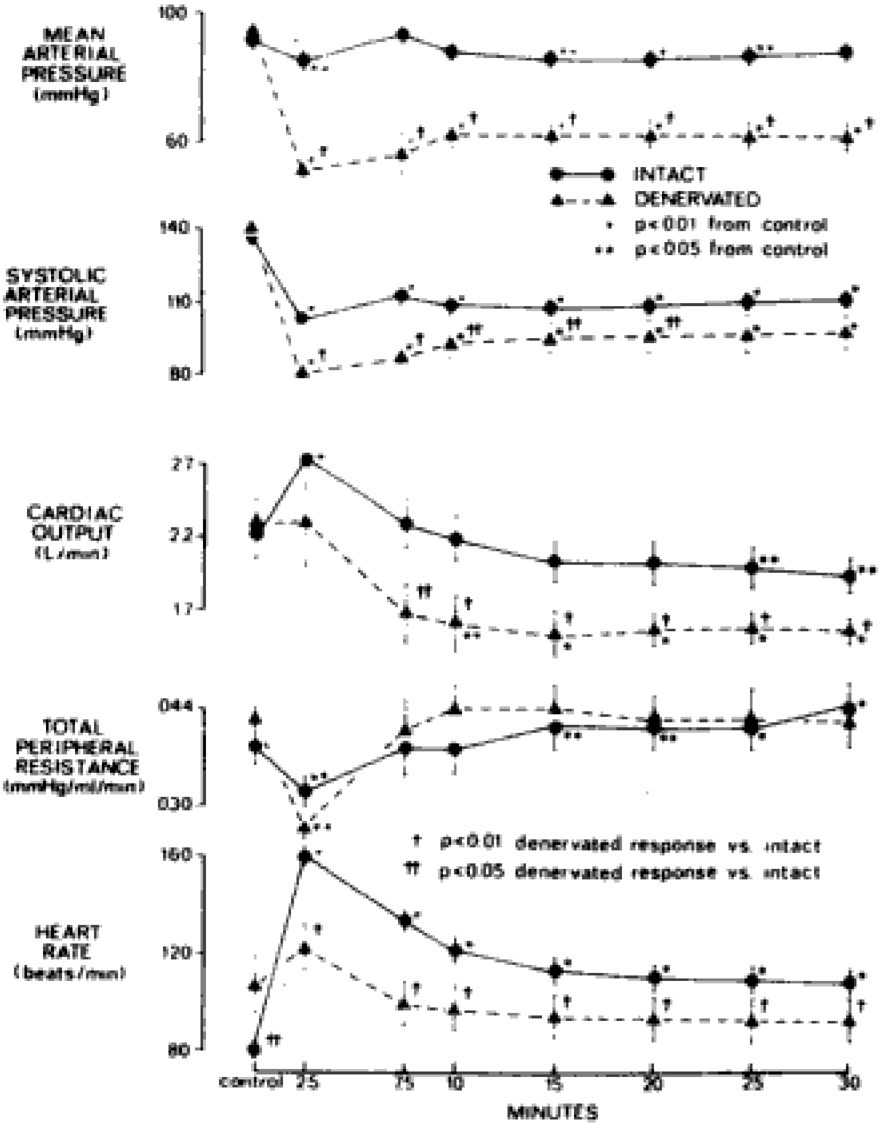


FIG. 12.2—Effects of pentobarbital, 30 mg/kg intravenously, on mean arterial pressure, systolic arterial pressure, cardiac output, total peripheral resistance, and heart rate of intact dogs ($n = 9$, solid lines) and denervated dogs ($n = 7$, dashed lines). * = changes significantly different from control. † = responses of denervated dogs that are significantly different from those of intact dogs. I = ± SEM. Intact dogs were able to maintain arterial pressure better than denervated dogs. In both cases systolic arterial pressure fell significantly. The heart rate response in the denervated dogs was qualitatively different from that of the intact ones, since heart rate failed to rise in the denervated dogs (Manders and Vatner 1976).

be mediated by arterial pressoreceptor reflexes rather than by a vagolytic effect of pentobarbital (Manders and Vatner 1976).

In the calf, cardiac output does not appear to change significantly following IV injection of a relatively small dose of pentobarbital (Anderson et al. 1972). However, a transient but significant effect upon pulmonary and systemic circulations may occur following administration of this anesthetic. A pressor response of the pulmonary circulation is observed, which may be attributable to a local vasoconstrictor effect on resistance vessels. In contrast to a pulmonary pressor effect produced by pentobarbital in cattle, it appears to have no effect upon the resistance vessels of pulmonary circulation in dogs. Pentobarbital appears to have a varying effect on systemic circulation (Anderson et al. 1972). These authors consistently observed tachycardia, which also has been seen in other species.

The incidence of ventricular fibrillation is increased, especially when animals are subjected to both anesthesia and hypothermia (Blair 1969). Ventricular fibrillation may occur in 100% of the hypothermic animals following administration of pentobarbital. It occurs in 50% of the animals following administration of thiopental.

In contrast to thiamylal-halothane anesthesia, the arrhythmogenic dose of epinephrine, dopamine, or dobutamine necessary to produce ventricular arrhythmia during pentobarbital anesthesia is greater in normothermic dogs (Bednarski and Muir 1985).

Consequently, pentobarbital does not sensitize the myocardium to catecholamine-induced arrhythmia.

The vascular system, especially the vasomotor center, is affected more by the concentration of barbiturate acting on it than by the total dose given. Rapid IV injection of a relatively safe dose of barbiturate causes a sharp but transitory fall in arterial pressure because of the high concentration briefly depressing the vasomotor center. Large IV doses depress the vasomotor center, resulting in peripheral vasodilation with a severe drop in arterial pressure. Excessive IV concentrations of barbiturates may injure capillary musculature directly to such an extent that sufficient capillary dilation occurs to induce vascular shock.

Pentobarbital and streptomycin interact to induce vasodilation in the perfused kidney and other vessels of the dog. Administration of Ca^{++} antagonizes the renal vascular effects of streptomycin (Wolf and Wigton 1971). IV injection of Ca^{++} antagonizes the hypotensive effects of streptomycin during pentobarbital anesthesia in dogs. Consequently, the inhibitory effects of aminoglycoside antibiotics on Ca^{++}-dependent vascular functions appear to contribute to their hypotensive activity in intact animals (Adams et al. 1976).

There is indication that pentobarbital also influences myocardial performance by Ca^{++}-dependent mechanisms; e.g., it appears to decrease binding availability of Ca^{++} at superficial membrane sites in cardiac cells (Nayler and Szeto 1972). Since aminoglycoside antibiotics such as streptomycin, neomycin, and possibly others also alter Ca^{++}-dependent functions, it is most likely that interaction with pentobarbital occurs. Such an interaction should induce a severe cardiodepressant effect, especially upon the myocardial contractile mechanism.

Intra-arterially, barbiturates, in particular thiopental, produce spasm of the arterial wall to the extent that massive gangrene occurs. Accidental intra-arterial injection of barbiturates has occurred on a number of occasions in humans and has resulted in the loss of fingers or the arm from thrombosis and gangrene. Thiopental has been shown to cause vasoconstriction in the perfused rabbit ear; this effect was associated with release of norepinephrine from the arterial wall. Under no circumstances should barbiturates, especially thiobarbiturates, be injected intra-arterially for induction of anesthesia. In humans, effects of an inadvertent, intra-arterial injection can be significantly minimized or completely prevented by using a solution of thiopental no greater than 2.5%.

A congenital porphyrin condition ("pink tooth") is sometimes observed in cattle. Porphyrin metabolism may be disturbed in normal animals from exposure to chemicals such as hexachlorobenzene, griseofulvin, and aminopyrine. In the liver, synthesis of porphyrin comes about by condensation of succinyl coenzyme A with glycine to form aminolevulinic acid. Formation of this acid occurs in the mitochondria of hepatic cells through enzymic activity (i.e., aminolevulinic acid synthetase). Barbiturates stimulate greater production of this enzyme, which increases porphyrin production. Death may occur in humans because the rise in porphyrin levels leads to neurologic disturbances from demyelination of peripheral and cranial nerves. Animals afflicted with a known or suspected disturbance in porphyrin metabolism should not be subjected to a barbiturate anesthetic.

Caution should be taken during administration of barbiturates in animals that have had extensive blood loss. The anesthetic induction dose may decrease from 28 to 38% after severe hemorrhage (Weiskopf and Bogetz 1985).

Gastrointestinal (GI) Tract. As a group, barbiturates appear to depress activity of intestinal musculature. However, after an initial depression, thiobarbiturates may increase both tonus and motility. After years of clinical use, no important effects such as diarrhea or intestinal stasis have been noted.

Kidney. The barbiturates appear to have no direct effect upon the kidney. Lack of renal function does not appear to alter the pharmacokinetics of pentobarbital (Davis et al. 1973). According to Davis and coworkers, the anesthetic can be used in dogs with impaired renal function. Pentobarbital elimination is normal in humans afflicted with renal failure (Reidenberg et al. 1976). However, sensitivity of animals to barbiturates may be increased by uremia; e.g., pentobarbital, hexobarbital sodium, and other barbiturate sleeping times are increased in uremic animals. This interesting phenomenon is due to a decreased capacity of the plasma protein for binding acidic drugs such as barbiturates.

By lowering blood pressure, barbiturates can indirectly produce oliguria or anuria. Only when prolonged, as in overmedication, does this effect become important. A drop in renal blood flow of as much as 42% may occur up to 1 hour following pentobarbital anesthesia.

There is some evidence that phenobarbital and occasionally pentobarbital inhibit water but not saline diuresis in dogs, possibly through an influence upon the antidiuretic hormone.

Barbital, a long-acting barbiturate, is excreted primarily unaltered in urine. The substituent group on carbon 5 of phenobarbital (also a long-acting barbiturate) is resistant to oxidation by the liver or other tissues. Unaltered long-acting barbiturates are excreted slowly over several days, which accounts for their prolonged periods of action. This slow excretion may lead to cumulative toxicity when an excessive dose is administered repeatedly. In the dog, about 20–25% of the total dosage of barbital is excreted in urine in the first 24 hours. A total of 85% is excreted in urine in 6 days.

In humans, as much as 50% of a dose of phenobarbital is excreted by the kidney in the unaltered form (Harvey 1975). Clearance of phenobarbital is considerably greater in alkaline than in acid urine. In carnivores, alkalinization of urine with sodium bicarbonate increases the elimination rate of long-acting barbiturates. Use of sodium bicarbonate and diuretics is clinically useful in treatment of intoxication from long-acting barbiturates.

Renal damage interferes with excretion of long-acting barbiturates. There is real danger of severe depression and death when these drugs are administered to a patient with impaired renal function.

Chickens will recover from pentobarbital anesthesia, but the avian kidney excretes barbital so slowly that they die in coma from respiratory failure. Since intermediate and long-acting barbiturates are detoxified over a prolonged period, they are not recommended for anesthetic use in avian or mammalian species.

Liver. Therapeutic doses of barbiturates have no significant effect upon liver function. In patients with liver damage, large doses of barbiturates may cause further injury. The detoxifying action of the liver has been discussed above under the fate of barbiturates.

Uterus and Fetus. Sedative doses of barbiturates do not influence uterine activity. Full anesthetic doses are believed, on the basis of in vitro studies, to depress uterine contractions during parturition. However, an equally if not more important consideration is the effect of barbiturates upon the fetus. Most barbiturates that have been studied can traverse the placenta with relative ease (Mirkin 1975). Equilibrium between maternal and fetal circulations is established within a few minutes in most circumstances.

Pentobarbital and thiopental in concentrations that fail to produce maternal anesthesia will completely inhibit fetal respiratory movements without maternal hypoxia prevailing. However, thiopental is not as depressant to the fetus as pentobarbital. Even though respiration is not completely depressed in a newborn animal following use of a barbiturate, there is no assurance that the animal will survive. A number of studies have revealed that the liver in the newborn of a number of animals lacks the microsomal enzyme system required to biotransform or metabolize drugs such as barbiturates. This important enzyme mechanism usually begins to develop during the 1st week following birth and does not attain maximal development until 8 weeks of age or older. Without this important enzyme mechanism to assist in degradation of barbiturates, the animal must depend primarily on renal elimination of the drugs. Even this route poses a problem because renal function in the newborn is less efficient than in the mature animal. Clinically, it is well known that a cesarean section performed solely under barbiturate anesthesia will depress the fetus and may produce up to 100% fetal mortality.

Hormone Release, Metabolism, and Clearance. In the rat, it is well established that the luteinizing hormone (LH) and follicle-stimulating hormone rise concomitantly on the afternoon of proestrus and that injection of pentobarbital just before onset of the spontaneous gonadotropin surge prevents this release from taking place. This phenomenon is referred to as pentobarbital-blockade (Chappel and Barraclough 1976). LH release is either suppressed or delayed in the normal, cycling female baboon (*Papio* sp.) by pentobarbital following IM injection of 35 mg/kg (Hagino 1979).

Pentobarbital anesthesia also depresses plasma LH concentration in the hamster and markedly elevates plasma concentrations of progesterone and cortisol in sheep. Use of pentobarbital in combination with halothane elevates progesterone and cortisol plasma levels in the ewe (Green and Moor 1977). Since barbiturates reduce both renal and hepatic blood flows, reduction in hepatic metabolism and renal excretion of steroids is partially if not principally responsible for the increase in plasma concentrations of progesterone and cortisol.

Metabolic Rate. Sedative doses of barbiturates do not significantly influence the basal metabolic rate. Doses producing surgical anesthesia depress basal metabolism so that less body heat is produced during anesthesia concurrently with excessive heat loss as a result of vasodilation. It is important that surgical patients anesthetized with barbiturates be kept warm while depressed, especially when overmedicated. Consequently, it is always wise to monitor the effect of barbiturate anesthesia upon body temperature (Chenoweth and Van Dyke 1969). With a decline in heat production during anesthesia and an increase in heat loss owing to peripheral vasodilation, the anesthetized animal drifts toward the temperature of the surrounding environment (Lutsky 1969). A definite hypothermic state is seen when the anesthetized dog is exposed to air temperatures below 27°C (Dale et al. 1968); rectal temperature decreases from 1 to 5° at an air temperature of 27°C to 10–18° at an air temperature of 10°C. This not only results in prolongation of recovery from pentobarbital anesthesia but deaths also occur. During winter energy shortages, lower room temperatures in operating and recovery rooms have been responsible for inducing hypothermia and delayed recovery from anesthesia in small animals (Waterman 1975).

Skeletal Muscle. Barbiturates (particularly pentobarbital) suppress sensitivity of the motor endplate of skeletal muscle to acetylcholine (Seyama and Narahashi 1975). However, barbiturates do not completely relax the abdominal musculature. If additional relaxation is required in surgery, curariform agents may be used. Since skeletal muscle relaxants are not analgesics or anesthetics, caution in using them under the guise of anesthesia must be avoided for humane reasons. The photomotor reflex should be checked to determine whether an animal is regaining consciousness when a skeletal muscle relaxant is used in conjunction with a barbiturate anesthetic.

In the horse, postanesthetic forelimb lameness believed to be due to muscular ischemia during the recumbent phase of anesthesia has been observed in animals subjected to barbiturate and inhalant anesthetics (Trim and Mason 1973).

Absorption. Barbiturates are absorbed readily from the GI tract. The rate of absorption varies but in general is faster for short-acting and slower for long-acting drugs. Although intrathoracic administration of barbiturates is not recommended, absorption following this route is quite rapid.

After IV injection, pentobarbital in plasma reaches distribution equilibrium in the brain within 3–4 minutes.

Distribution. Barbiturates are distributed more or less generally throughout the body. Values for the specific volume of distribution (V′d) have not been determined for many barbiturates. Not only would these values differ for different barbiturates but also among the various species. In the goat, the V′d for pentobarbital (30 mg/kg) administered intravenously is 0.72 L/kg; the first-order disappearance rate kinetic constant (Kd) is 0.76 hour and the half-life ($t_{1/2}$) is 0.91 hour (Boulos et al. 1972). In the dog, the elimination-phase half-life (8.2 ± 2.2 hr) of pentobarbital is considerably longer (Frederiksen et al. 1983).

Thiopental, a highly lipid soluble drug, passes readily through the blood-brain barrier. Soon after IV injection, its concentration in cerebrospinal fluid and plasma of the dog is found to be nearly equal. Phenobarbital and barbital have low partition coefficients and penetrate the blood-brain barrier much more slowly. CNS depression does not occur until 15 minutes or longer following IV administration of these compounds.

Thiobarbiturates are initially present in quite high concentrations in highly perfused tissues (e.g., the brain), resulting in rapid induction of general anesthesia. Thiobarbiturates then redistribute to the moderately perfused body tissues (such as muscle). This redistribution to moderately perfused tissues decreases the brain concentration to a level which allows the animal to regain consciousness. Further redistribution to adipose tissue from both highly and moderately perfused tissues results in the complete recovery from thiobarbiturate anesthesia. Since sighthounds (e.g., Greyhounds) have a lower percentage of adipose tissue, their complete recovery from the thiobarbiturates is delayed. Other patients with cachexia or with extremely low body fat would also be expected to have prolonged recoveries from thiobarbiturates (Price et al. 1960; Paddleford 1988).

Barbiturates diffuse through the placenta into fetal tissue and may occur in the milk in small amounts. It is possible to detect minute amounts of barbiturates in body fluids such as plasma and urine as low as 500 pg/mL using radioimmunoassay procedures (Flynn and Spector 1972).

Fate. Barbiturates are eliminated by renal excretion in urine and/or destroyed by oxidative activity of hepatic and extrahepatic tissues. Trace amounts may be excreted in milk of a lactating female.

TABLE 12.2—Degradation of barbiturates by liver, brain, and muscle brei (120 µg of appropriate barbiturate added to all samples)

Barbiturate	Percentage liver destruction	Percentage brain destruction	Percentage muscle destruction
Seconal	30	0	0
Pentothal*	53	10	0
Phenobarbital	0	0	0

HEPATIC METABOLISM. Pentobarbital and many other barbiturates are metabolized principally by the hepatic microsomal enzyme system (Freudenthal and Carroll 1973). Disappearance of pentobarbital from plasma of dogs is attributed to biotransformation of the drug by the liver as well as redistribution to muscle and adipose tissue. Pentobarbital is 3-hydroxylated or oxidized by liver microsomes. Evidence indicates that oxidative metabolism is not necessarily impaired in patients with poor renal function (Reidenberg et al. 1976).

Approximately 50% of the dose of pentobarbital given is recovered in urine as the 3-hydroxy metabolite. The rate of hydroxylation or oxidation of pentobarbital is increased markedly by pretreatment with phenobarbital. Thiobarbiturates are destroyed by the liver and extrahepatic tissues, especially in brain and kidney. Their destruction in the extrahepatic tissues is more rapid than for any other barbiturates (see Table 12.2). Oxybarbiturates are metabolized by the liver.

The rate at which thiobarbiturates are metabolized is not as rapid as previously thought. Originally, their brief action was believed to parallel the rate of destruction by the liver and extrahepatic tissues. Metabolism of thiopental is too slow to account for its rapid disappearance from plasma. Later it became apparent that the systemic action of the thiobarbiturates was quickly terminated by redistribution from the brain to other body tissues.

Short-acting barbiturates are not recovered from urine following sedative doses and in only trace amounts at higher doses. Activity of these drugs is brief because of rapid tissue oxidation. Additional evidence of the importance of the liver in destruction of many barbiturates is the clinical finding that anesthesia with a short-acting barbiturate may be prolonged many times in the presence of hepatic injury or disease. The clinician should therefore avoid use of short-acting barbiturates in patients showing liver disturbances. A dose of thiopental or a comparable ultrashort-acting barbiturate producing anesthesia in a normal patient for only about 15 minutes may anesthetize a patient with impaired liver function for several hours.

Studies have shown that a number of drugs, including pentobarbital, are metabolized by hepatic microsomal enzymes (Conney 1967), which are located in the endoplasmic reticulum. Activity of drug-metabolizing

TABLE 12.3—Effects of certain barbiturates injected intravenously in dogs

*anesthesia = absence of pad reflex.
†Down time = from onset of anesthesia until animal stood.
§Return to normal = from onset of anesthesia until the dog could climb stairs without ataxia.

enzymes in hepatic microsomes may be affected by several factors; e.g., newborn and young animals possess only a fraction of the capability of adult animals to metabolize drugs, and starving the animal significantly depresses the activity of hepatic microsomes to metabolize drugs. Liver microsomal activity may be accelerated by administration of various drugs (e.g., phenobarbital, phenytoin) to the degree that the same drug or others may be metabolized at a greater rate; e.g., phenobarbital has the capability of stimulating metabolism of other barbiturates. Consequently, animals become resistant or tolerant to these drugs because of a greater rate of metabolism of the barbiturate to inactive metabolites. This phenomenon has been noted in rats pretested with phenobarbital; they were anesthetized only 11 minutes by hexobarbital compared to 216 minutes for the control group. Chemical agents such as DDT and other chlorinated pesticides can affect duration of anesthesia produced by pentobarbital; DDT administered 2 days prior to pentobarbital reduces duration of anesthesia in animals by 25–50% (Conney and Burns 1972).

After exposure to phenobarbital, it may take up to 7 months for the complete disappearance of enzyme induction in the dog. Once initiated, it may continue for a long period.

SPECIES VARIATION. The rate of metabolism of barbiturates varies considerably between and among various species; e.g., the mouse metabolizes hexobarbital many times faster than humans. In general, most laboratory animals metabolize drugs more rapidly than humans. The cat, however, is an exception and requires a longer time to metabolize barbiturates. Pentobarbital is metabolized at a rate of 4%/hr in humans compared with 15%/hr in dogs and 50%/hr in horses. In ruminants, particularly sheep and goats, pentobarbital is metabolized at a rapid rate (Bryant 1969). In sheep, pentobarbital is cleared from plasma at the rate of about 49%/hr, and thiopental is cleared at about 17%/hr following tissue equilibrium. The mean biologic half-life of pentobarbital in the plasma of sheep is 66.8 ± 16 minutes (Santos and Bogan 1974). The difference in the rate of metabolism is the primary cause of the differences in the duration of action seen when pentobarbital is administered to various species. The reappearance of CNS reflexes occurs at similar plasma levels after pentobarbital anesthesia in goats and dogs, but the time for the return of those reflexes is much longer in dogs (Davis et al. 1973).

Pretreatment of sheep with phenobarbital does not influence in vitro metabolism of hexobarbital or pentobarbital (Shetty et al. 1972). Apparently, sheep are incapable of inducing a more rapid rate of metabolism in an already active microsomal enzyme system.

Tolerance. Dogs become tolerant to several barbiturates as determined by the reduction in anesthesia time of a given and frequently repeated dose. Cross-tolerance for all barbiturates occurs with a tolerance developed to one barbiturate. Tolerance is soon lost by withdrawal of the drug.

This is known as pharmacodynamic tolerance. As applied to barbiturates, this involves adaptation of nervous tissue to the presence of the drug (Harvey 1975).

Development of tolerance to barbiturates in dogs would be of interest only in clinical cases where sedative doses of barbital or phenobarbital have been given regularly for prolonged periods.

Stimulation or induction of microsomal enzyme activity in the liver markedly affects duration of action of barbiturates. The so-called development of tolerance that occurs after a brief exposure to barbiturates in low dosage is due to enhancement of microsomal enzyme activity.

Duration of Depressant Effect. Duration of action of two IV barbiturates (pentobarbital, thiopental) commonly used in veterinary medicine is illustrated in Table 12.3. The same depth of surgical anesthesia was obtained for all drugs, with a dosage carefully determined by previous trials.

Duration of the depressant actions of orally administered barbiturates is illustrated in Fig. 12.3, which is based on more than 1000 trials in dogs (Swanson 1944). Other factors to be considered are nutritional status, age, and individual variations in the animal. A starved animal is much more sensitive to barbiturates because of a reduced ability to metabolize them (Chenoweth and Van Dyke 1969). Neonates and young animals are less able to metabolize barbiturates than adults and therefore will be anesthetized much longer

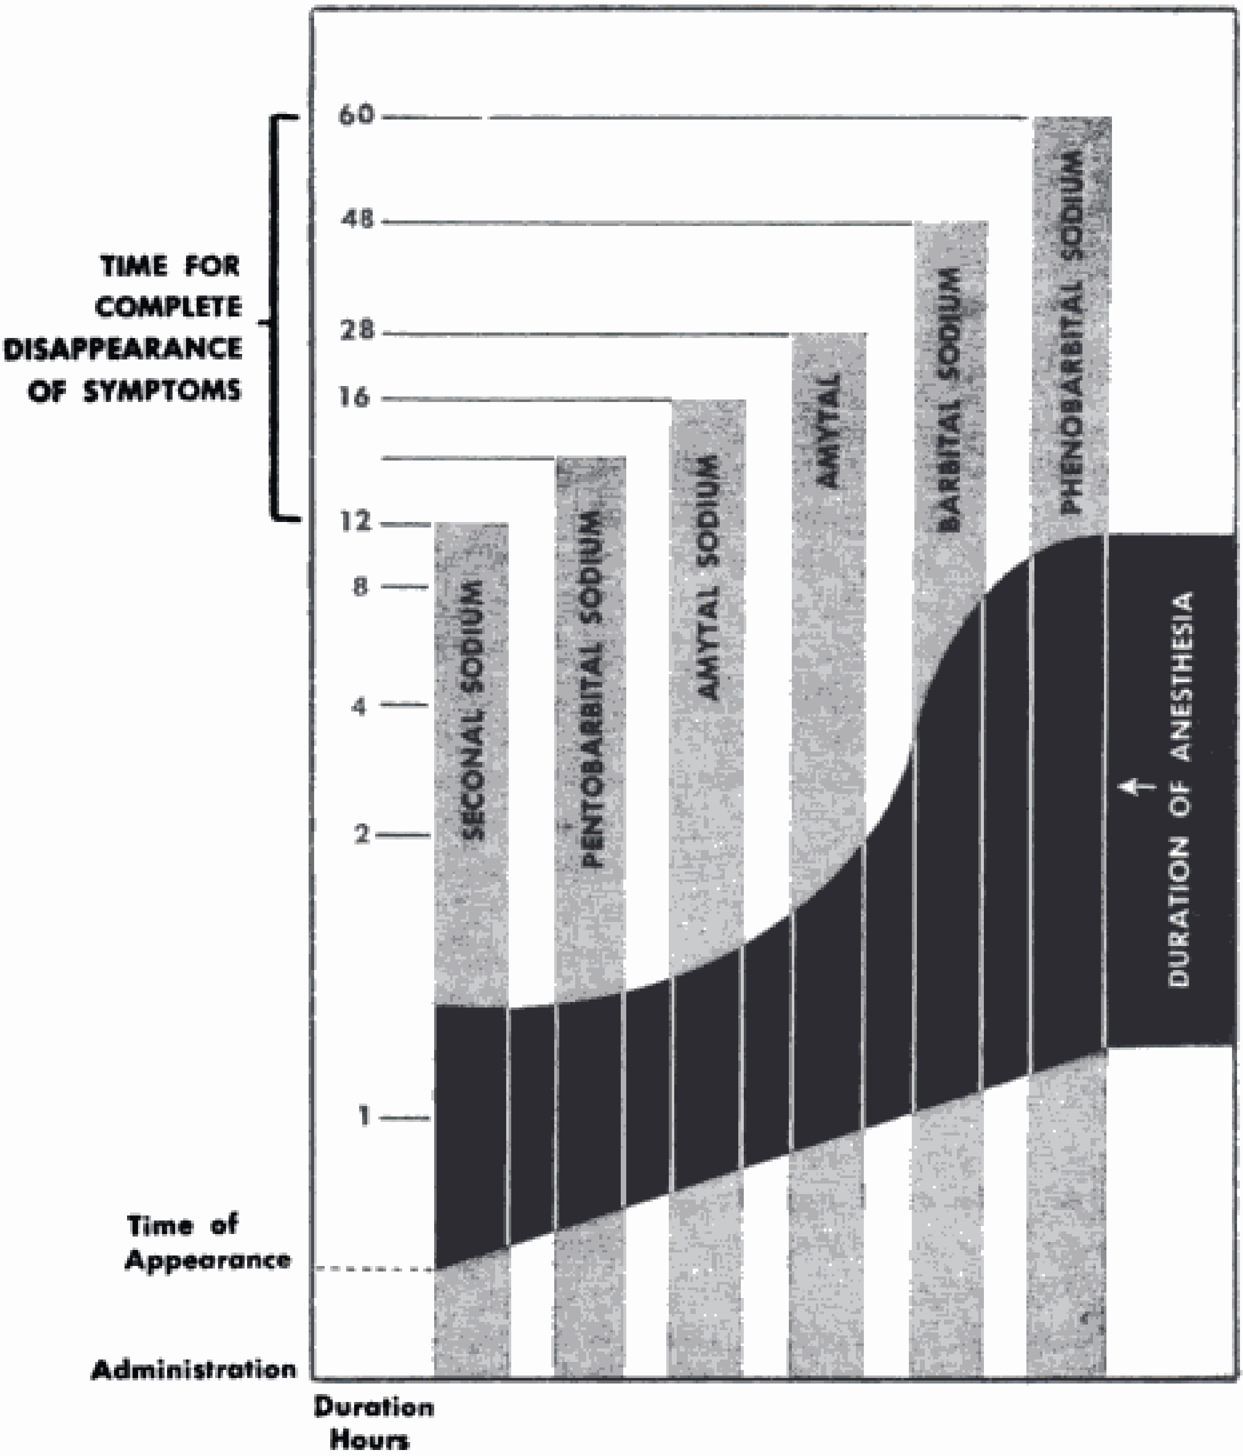

FIG. 12.3—Time of appearance, duration of anesthesia, and time needed for complete disappearance of symptoms after oral administration of equivalent single anesthetic doses in animals (Swanson 1944; courtesy of the Lilly Research Laboratories).

and recover more slowly from the depressant effects. Even the influence of circadian rhythm can appreciably affect the depth of depression and duration of anesthetic action (Simmons et al. 1974). In nocturnal animals such as laboratory rodents, the hazard of drug-induced mortality is increased at night and recovery is prolonged. Individual variations exist not only because of age, sex, weight, and nutritional status but also with respect to the degree that microsomal enzyme induction is affected; this may vary qualitatively and quantitatively among individuals as well as among species (Chenoweth and Van Dyke 1969).

In addition to species variation, there are differences within the breeds of animals with respect to duration of action of barbiturates. For example, thiobarbiturates induce longer anesthetic effects in Greyhound dogs than in mixed breeds (Sams et al. 1985). Methohexital, an oxybarbiturate, induces a shorter period of anesthesia in the Greyhound than thiobarbiturates such as thiopental or thiamylal.

As long ago as 1962, it was known that chloramphenicol could prolong the hypnotic action of hexobarbital in mice and slow its rate of biotransformation. Duration of the depressant effect of pentobarbital is prolonged by pretreatment or concurrent administration of chloramphenicol (a broad-spectrum antibacterial agent) in the mouse, rat, dog, cat, and monkey (Adams 1970; Adams and Dixit 1970; Teske and Carter 1971). Chloramphenicol suppresses or inhibits hepatic microsomal enzyme activity. If it is given immediately preceding administration of pentobarbital in the dog and cat, a 120% increase in duration of anesthesia occurs. This effect can be produced by relatively small quantities of chloramphenicol and can be detected as long as 24 days following the last administration of the antibiotic agent.

If an animal has had a recent history of being treated with chloramphenicol, pentobarbital should not be used for induction of anesthesia for at least 25 days following. Since duration of anesthetic action of thiobarbiturates does not appear to be affected by chloramphenicol (Adams and Dixit 1970), their use should be safer for induction of anesthesia, followed by maintenance of anesthesia with inhalant anesthetics. Nevertheless, it is advisable to use thiobarbiturates conservatively following administration of chloramphenicol. Studies in mice given chloramphenicol sodium succinate simultaneously with thiamylal indicate that sleep is about 10 times longer compared with sleeping time in animals given thiamylal alone (Azadegan et al. 1980).

The anesthetic action of barbiturates, but not of other common depressants, can be potentiated by IV or intraperitoneal injection of dextrose; fructose; intermediary metabolites such as lactate, pyruvate, and glutamate; and a few other substances of diverse nature. The lactate, pyruvate, and glutamate are known to increase the rate of entrance of barbital into the brain and thus increase cerebral depression. It is probable that dextrose, fructose, and other substances act similarly. This reaction can be inhibited by administration of acetylcholine, which decreases cell permeability and entrance of barbital into the cortex. Clinically, about one-fourth the dogs just recovering from pentobarbital anesthesia can be reanesthetized by IV injection of 550 mg/kg lactate; about one-half will give a partial response, and the remaining one-fourth are refractory.

Other studies reveal that doses of glucose of 200 to greater than 600 mg/kg administered intravenously in the dog fail to influence the mode of respiration or the electroencephalogram (EEG) shortly after induction of surgical anesthesia with pentobarbital (Hamlin et al. 1965). Fear of embarrassing ventilation or depression of cortical activity through a "glucose effect" should not contraindicate infusion of glucose. However, this conclusion may require some modification (Hatch 1966). According to Hatch's study, rapid IV administration of glucose in the dog that is regaining voluntary movement from thiopental anesthesia results in immobilization of 11% of the subjects. This period of apparent reanesthetization represents about a 50% increase in sleep time. Sodium lactate causes a similar reimmobilization in 39% of the dogs, with approximately 50% increase in sleep time. Epinephrine produces reimmobilization in about 85% of the animals with an extension of about 40% in total sleep time. Hatch (1966) concluded that the possibility of producing reanesthetization with glucose, sodium lactate, and epinephrine need be of no practical concern as long as these substances are used properly. Improper use of these compounds, especially in the presence of longer acting barbiturates, could lead to a dangerously prolonged period of incapacitation.

Influence of adrenergic agents upon recovery of dogs anesthetized with thiopental and methohexital sodium has been studied by Heavner and Bowen (1968). Administration of epinephrine and isoproterenol at the time dogs are recovering from thiopental anesthesia results in reanesthetization. This effect is not seen in animals recovering from methohexital anesthesia. Reanesthetization of dogs recovering from thiopental has not been associated with α- or β-adrenergic activity. Heavner and Bowen (1968) believe there is a possibility that epinephrine produces a peripheral analgesic action that is responsible for the reanesthetization because depression of the sensory electroneurogram of the superficial radial nerve is induced.

Reinduction of thiopental anesthesia is also induced by administration of high doses of aspirin and phenylbutazone in the rat (Chaplin et al. 1973). These nonsteroidal anti-inflammatory agents displace thiopental from rabbit plasma proteins in vitro. It is unlikely that reinduction of anesthesia by these agents is as marked in animals that have received pentobarbital because its binding to sheep plasma (36%) is less than the binding of thiopental (67%). Nevertheless, the sleep time of pentobarbital in small laboratory rodents can be significantly increased by sulfonamides (sulfanilamide, sulfamethazine, sulfaethylthiazol), salicylic acid, acetylsalicylic acid (aspirin), sodium salicylate, and doxycycline. All these drugs displace pentobarbital and other barbiturates from plasma proteins, which leads to an increased blood level of unbound barbiturate for further depressant effect upon the CNS. With the increasing number of pharmacologic agents used in therapeutic procedures, the clinician needs to be alert to these potential drug interactions.

Even the type of bedding upon which an animal is kept has a marked effect on anesthetic dosage and duration of anesthesia. Softwood bedding such as cedar or pine shavings induces drug-metabolizing enzymes in the liver, thus reducing the period or duration of anesthesia.

Duration of the depressant effect of barbiturates is also generally increased (except for barbital) by hypothermia (Blair 1969); the activity of pentobarbital is greatly enhanced, and sleeping time in the dog at a body temperature of 27°C is 3.5 times that of the normothermic sleeping time. Consequently, about one-third of the normal dose of pentobarbital is required to maintain a specified level of anesthesia at this temperature (Blair 1969). Inadvertent hypothermia can be avoided by frequent or continuous temperature monitoring and by employing warming boards, water mattresses, or other such devices (Lutsky 1969).

Use of thiobarbiturates in maintenance of anesthesia cannot be supported or condoned (Dodman et al. 1984). Their continuous use in maintenance of anesthesia will result in prolonged and unfavorable recovery.

Anesthetic-Antibiotic Interaction. In cats anesthetized with pentobarbital, administration of neomycin induces a complete neuromuscular paralysis (Adams and Mathew 1974), which is believed to be due to the persistent binding by neomycin of Ca^{++}-receptive sites at the motor end plate of skeletal muscle. Apnea and death have also occurred in a dihydrostreptomycin-treated dog that was originally breathing spontaneously during recovery from pentobarbital anesthesia (Adams and Bingham 1971). The above examples illustrate problems that may occur in a patient seemingly recovering uneventfully from anesthesia and surgery. The margin of safety of neuromuscular transmission should be considered when anesthetics, neuromuscular blocking agents, and antibiotics that depress neuromuscular function are employed in multiple drug regimens (Adams et al. 1976).

The effect of chloramphenicol upon suppression of microsomal enzyme activity and the depressant effect of pentobarbital anesthesia has been discussed.

Margin of Safety. All barbiturates seem to possess approximately the same margin of safety between the anesthetic dose and the median lethal dose (LD_{50}). Using recommended techniques of administration, 50–70% of the LD_{50} is needed to anesthetize an animal. Apparently no barbiturate possesses a markedly advantageous margin of safety over any other when the anesthetic dose and the LD_{50} are compared. However, fewer postanesthetic complications follow use of the shorter acting barbiturates because of the reduced incidence of hypostatic congestion, which often leads to cardiopulmonary as well as other complications.

Toxicology. Barbiturates produce death by depression of the respiratory center, which leads to cessation of respiration. As the severity of CNS depression progresses, respiration becomes shallow and slow. The pupils dilate as hypoxia develops. A weak and rapid pulse exists. Reflexes disappear and the skin is cold and cyanotic. Sometimes the respiration stops abruptly following too rapid IV injection of a barbiturate; following this, the heart continues to beat briefly until hypoxia and hypercarbia cause cardiac arrest. More often, breathing continues at a progressively depressed rate and amplitude until it stops within a few minutes after the drug is given. Mechanical obstruction of the airway must be avoided, especially in brachiocephalic breeds of dogs. Artificial respiration with 100% oxygen should be administered to prevent hypoxia. Although less reliable than use of oxygen, doxapram or other analeptic drugs may be used to stimulate the respiratory center.

Shorter-acting barbiturates such as pentobarbital are largely destroyed by the liver and therefore should not be administered to animals with hepatic disease. Patients suffering from shock and toxemia have a lesser margin of safety than normal animals. The newborn cannot metabolize barbiturates as readily as adults and consequently have a lesser margin of safety and are subject to more prolonged effect.

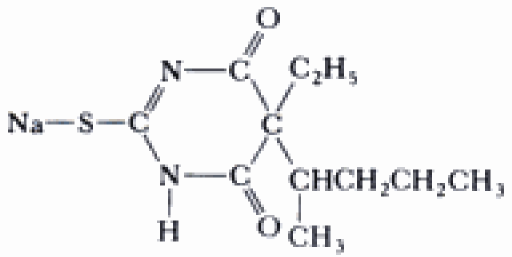
When barbiturates are injected intravenously, the lethal dose varies inversely with rate of injection. The more rapid injection results in a higher local blood concentration that is able to paralyze the vital medullary centers. The amount administered actually would not be a lethal dose if injected slowly. Fatal doses of pentobarbital cause some inflammation of the vital organs, congestion of the brain and meninges, and perivascular hemorrhage and edema.

A drug interaction has been reported in mice treated with cyclophosphamide, a potent antineoplastic agent of the mustard family, and barbiturates (hexobarbital, phenobarbital, pentobarbital). An increased lethality occurs when barbiturates are administered concurrently with cyclophosphamide (Rose et al. 1973). Since cyclophosphamide is being used increasingly as an antineoplastic agent in animals, the clinician must remember to omit use of all barbiturates in such cases.

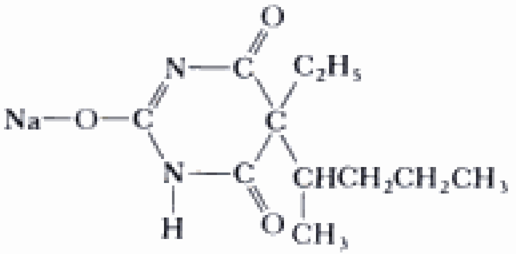
Pentobarbital Sodium. Immediately after its introduction, *Pentobarbital Sodium*, USP (Nembutal sodium, Pentobarbitone sodium, Sagatal, Napental), was widely accepted in veterinary medicine as a surgical anesthetic. At one time it was the most widely used anesthetic agent in small animals.

The structure of pentobarbital is similar chemically to thiopental sodium. The presence of the oxygen atom in the pentobarbital molecule instead of a sulfur atom is the differentiating characteristic of the two barbiturates (see Fig. 12.4 for the comparative structural formulas). The human formulation (Nembutal) uses propylene glycol as a vehicle and has been associated with intravascular hemolysis when administered intravenously to animals at doses sufficient to produce anesthesia.

ADMINISTRATION AND ORAL DOSAGE. Pentobarbital can be administered orally to carnivora to produce sedation. If the stomach is empty, the drug may be given orally to produce surgical anesthesia in about 0.5 hour at a dose level of 28–30 mg/kg. Oral administration in food produced lateral recumbency in five of six dogs in an average of 59 minutes at an average dose of 63 mg/kg (Ramsay and Wetzel 1998).



Thiopental Sodium



Pentobarbital Sodium

FIG. 12.4

INTRAPERITONEAL. Intraperitoneal injection of pentobarbital has been widely practiced in small animals but now is limited primarily to those difficult to restrain for IV injections, such as rodents and other small laboratory animals. The dose generally employed is 28–30 mg/kg up to 15–16 kg, but is reduced somewhat for heavier animals. Depression appears in about 15 minutes and persists in some measure 4–8 hours.

INTRAVENOUS. IV injection of pentobarbital is the most satisfactory method of administration for production of anesthesia. This route generally can be used in all species and is most often preferred in veterinary medicine where restraint of the patient is practicable. By this method the dose is not inflexibly set by weight but can be fitted to the individual susceptibility of the patient or administered "to effect" as judged by disappearance of normal reflexes.

The IV dose is determined by the response desired, and the drug is given until the desired effect is obtained. However, the anesthetic dose approximates 24–33 mg/kg. Once the anesthetic is injected, it cannot be removed. Duration of pentobarbital anesthesia in the dog is 1–2 hours (Leash 1969); 4 or more hours are usually required before an animal is ambulatory after an IV injection.

Injections should be made carefully to avoid accidental perivascular deposit of pentobarbital, since it irritates the tissues and occasionally causes sloughing. If a perivascular injection of the barbiturate inadvertently occurs, the area should be infiltrated with 1 or 2 mL 2% procaine hydrochloride or 2% lidocaine hydrochloride solution (Leash 1969). If these solutions are unavailable, infiltration with a physiologic saline solution may be of value in reducing tissue irritation and eventual sloughing.

An IV injection of a small dose of pentobarbital may be used to produce hypnosis or sedation to avoid the fright, excitement, and resistance to restraint that are so dangerous and objectionable in handling a patient. This sedation can be followed by a local or an inhalant anesthetic.

INTRAMUSCULAR. Pentobarbital has been suggested via the IM route in the dog (Leash 1969). Doses recommended are 20 mg/kg for basal anesthesia, 30 mg/kg for moderate anesthesia, and 40 mg/kg for general anesthesia. However, this route of administration is not recommended because of the likelihood of tissue irritation and variability in effect.

INTRATHORACIC. Barbiturates have been administered by the intrathoracic route to animals such as the cat. Since trauma, pleural irritation, and parenchymal necrosis of lung tissue can occur following the intrathoracic injection of barbiturates, this route is not recommended. This method is sometimes used for euthanasia of animals when IV or other routes are inaccessible.

CLINICAL USE. Although pentobarbital is used in a number of species, it is approved by the US Food and Drug Administration (FDA) for use only in the dog and cat.

DOGS AND CATS. Pentobarbital is frequently used as an anesthetic in the dog and cat. However, it is not without toxic effects that require constant alertness by the veterinarian. For brief anesthesia, pentobarbital is surpassed by the ultrashort-acting barbiturates of more recent introduction. For IV anesthesia in the dog, about 24–33 mg/kg of pentobarbital in about 3–6% aqueous solution should be used. The average IV dose for dogs is approximately 30 mg/kg. In the cat, the recommended IV dose is 25 mg/kg with an additional 10 mg/kg if the initial dose is inadequate (Strobel and Wollman 1969).

Approximately one-half the anticipated dose should be injected at a moderately fast rate so that stage II, or the excitement stage, of anesthesia is bypassed. A pause for a few seconds to 1 minute is recommended to allow the drug to exert its full effect. Thereafter, the pentobarbital must be injected to effect. It is administered slowly in repeated small amounts over a period of 2–4 minutes with continuous observation of reflexes and respiratory activity until the desired depth of surgical anesthesia is obtained. Induction of anesthesia intravenously is generally uneventful; however, delirium or excitement as seen in stage II may occur if the initial dose is inadequate.

Sometimes an IV injection must be stopped in the presence of shock or toxemia. A given level of anesthesia will persist for about half an hour, after which depression decreases, with complete recovery in 6–24 hours. Some dogs show considerable delirium or excitement during recovery, as manifested by whining, barking, attempts to stand or walk, and leg paddling movements. Narcotic analgesics or phenothiazine tranquilizers in combination with barbiturate anesthesia are often used to eliminate this undesirable behavior (Leash 1969).

Basically, the procedure for induction of pentobarbital anesthesia in the cat is similar to that described for the dog. The anesthetic dose of pentobarbital by the IV route is not appreciably different on a body weight basis than that of the canine species. Female cats (33 mg/kg) are more susceptible to action of pentobarbital than males (40 mg/kg). In the newborn kitten, pentobarbital is an inadequate anesthetic, since the depth of anesthesia is difficult to control and recovery time is extremely prolonged (Sis and Herron 1972). In the adult cat, recovery of the righting reflex after an IV dose of 30 mg/kg pentobarbital occurs in 270 ± 52 minutes; recovery of the corneal and flexor withdrawal reflexes occurs at 25 ± 8 minutes and 31 ± 11 minutes respectively (Child et al. 1972a).

Premedication. Sometimes it is difficult to intravenously inject an excitable dog or cat that has not been previously medicated with a depressant drug. Without administration of a preanesthetic agent, the average dog requires 28.6 mg/kg pentobarbital to become surgically anesthetized. Use of preanesthetic agents not only renders the animal easier to handle and treat but also decreases the amount of barbiturate up to 50% or more for surgical anesthesia and reduces the likelihood of excitement during recovery. Xylazine, used as a sedative preanesthetic agent, decreases the dose of pentobarbital necessary to induce anesthesia in dogs up to 78% (Hatch et al. 1983).

In severely toxic patients, pentobarbital alone should not be used to depress a patient beyond the beginning of light surgical anesthesia. It is much safer to use preanesthetics to reduce the amount of pentobarbital needed. In many instances the safest anesthesia in toxic patients is obtained by premedication with a narcotic analgesic or a short-acting barbiturate followed by an inhalant anesthetic. Atropine sulfate is an additional preparation that should be used routinely prior to barbiturate anesthesia.

Control of Convulsions. Pentobarbital is an important drug for relieving convulsive seizures, especially when caused by strychnine or other convulsants. IV administration is preferable because a better balance between convulsant and depressant influences can be obtained. In the dog, pentobarbital is antidotal to as much as 35 LD_{50} of strychnine.

Treatment with pentobarbital of convulsions induced by lidocaine hydrochloride in the dog results in a detrimental or lethal interaction (Caron and LeLorier 1979). It is quite well known that lidocaine, a local anesthetic, has general anesthetic properties. Studies in the late 1950s in humans revealed that IV lidocaine reduces the amount of barbiturate (thiopental) required to accomplish smooth anesthesia by 13%. Unlike phenobarbital, a dose of pentobarbital that will produce unconsciousness is needed to control seizures (Macdonald and Barker 1979).

Lethal Doses. The lethal dose of pentobarbital in the dog is 85 mg/kg orally and 40–60 mg/kg intravenously. Toxicosis, including death, has been reported in dogs fed uncooked meat from a horse euthanatized 8 days previously with pentobarbital (Polley and Weaver 1977). It is unlikely that cooking inactivates pentobarbital in meat, since the chemical is considered to be relatively stable. Animals euthanatized with pentobarbital and rendered in a steam-jacketed cooker for about 3 hours at 127–132°C show virtually no degradation of the drug (O'Connor et al. 1985).

Toxicosis in a bitch has been reported from ingesting a puppy euthanatized by pentobarbital (Fucci et al. 1986). Indiscriminate disposal of carcasses that contain large quantities of barbiturates should be avoided.

Euthanasia. Several barbituric acid derivatives may be used in euthanasia of small animals. Of the barbiturates, pentobarbital is most commonly used (Report of the AVMA Panel on Euthanasia 1993).

The lethal dose for dogs, administered intravenously, is generally regarded as 40–60 mg/kg or approximately double the dose used for surgical anesthesia. Both respiratory and cardiac arrest occur following successful euthanasia.

COWS AND HORSES. Pentobarbital will produce surgical anesthesia in the horse, mule, and cow as well as other large animals, but its use alone is not generally recommended. Some excitement may be noted, even with rapid induction. At the completion of IV injection of pentobarbital alone, the horse sometimes rears and falls over backward, injuring the poll. Pentobarbital produces prolonged periods of recumbency and usually excitement during recovery. Large animals make futile attempts to stand before they have recovered complete control of their locomotor activities, and dangerous struggling occurs.

Pentobarbital has been used with greater success in foals and small colts for sedation (e.g., while taking radiographs) and anesthesia. Minimal excitement occurs in some.

Pentobarbital can be used in large animals as a sedative, or it may be used preoperatively in combination with a local anesthetic. An IV dose of 1–4.4 mg/kg provides a marked sedative or hypnotic action, so with the aid of a local anesthetic, several standing operations can be performed if desired.

SWINE. Pentobarbital administered by IV injection provides reasonably good anesthesia in swine weighing less than 45 kg. Above this weight, pentobarbital appears to have a considerably lessened margin of safety. The tendency in the USA is to administer only sedative dosages of pentobarbital intravenously in heavy swine and to follow this with local anesthesia at the surgical site. Since respiratory depression is readily induced in swine following barbiturate anesthesia, hypoxia and hypoventilation can be prevented by use of oxygen.

IV dosages of pentobarbital should be fitted to each patient or administered to effect by observing the disappearance of reflexes. Slow injection of the solution is essential. Recovery generally requires 60–90 minutes. Pentobarbital appears to have a considerable margin of safety in pigs of 10–22.5 kg. It has been determined that 24 mg/kg produces anesthesia suitable for most kinds of surgery. For swine weighing over 99 kg, the IV dose should be no more than 19.8 mg/kg. For castration of a large boar where brief light anesthesia is required, only 9.9 mg/kg via the IV route is needed.

Pentobarbital is also administered intratesticularly to achieve anesthesia for castration procedures (Henry 1968). A dose of 1.5 mL (450 mg)/10 kg pentobarbital (300 mg/mL concentration or a 30% solution) is injected into each testicle with a maximum of 20 mL per testicle for a very large boar. Satisfactory anesthesia is achieved within 10 minutes after administration. It is recommended that the anesthetic solution be injected below the tail of the epididymis in the upper one-third of the testicle. After injection of the anesthetic, the animals become incoordinated in a few minutes. Recumbency occurs between 5 and 15 minutes following administration. As soon as no response is elicited upon pricking the scrotal skin with a needle, the castration procedure should be conducted as rapidly as possible. The unabsorbed anesthetic solution is eliminated with surgical removal of the testes, allowing for a more rapid and safe recovery. Recovery from anesthesia requires 20–40 minutes. To avoid fatal poisoning in dogs or other animals, the testes should be disposed of properly.

Preanesthetic medication not only reduces the amount of anesthetic required for major surgical procedures but facilitates handling of the pig prior to induction of anesthesia (Booth 1969). Preanesthetic medication in the pig consists of atropine (0.07–0.09 mg/kg), meperidine hydrochloride (1–2 mg/kg), and promazine hydrochloride (2 mg/kg). All preanesthetic preparations are injected intramuscularly in separate sites 45–60 minutes prior to administration of the anesthetic. It is often necessary to administer atropine at hourly intervals during anesthesia to prevent salivation and mucus formation in the respiratory tract.

IV pentobarbital (9 mg/kg) administered 2 minutes after IM ketamine (11 mg/kg) induces surgical anesthesia for 45 minutes in swine weighing up to 50 kg; atropine sulfate (0.05 mg/kg) and fentanyldroperidol (1 mL/13.7 kg) are administered intramuscularly as premedicants 10 minutes prior to administration of ketamine (Bauck 1984).

GOATS AND SHEEP. Pentobarbital has a short duration of action in ruminants compared to other species because of a more rapid microsomal oxidative metabolism. The initial IV anesthetizing dose (25 mg/kg) of pentobarbital in the goat should be administered slowly (Bryant 1969). Anesthesia will be deep for about 5 minutes and then become less until complete recovery occurs in 40–60 minutes. Duration of satisfactory anesthesia is about 20 minutes, which is sufficient time to catheterize the jugular vein for supplementary injections and to intubate the trachea. Compared to the dog, duration of anesthesia in the goat is much shorter for an equivalent level of anesthesia. It is preferable to use pentobarbital for induction of anesthesia in the goat and then to maintain it with an inhalant anesthetic after tracheal intubation.

In adult sheep, pentobarbital is rapidly metabolized, requiring additional increments to maintain anesthesia for more than 15–30 minutes. The drug is useful for induction of anesthesia; this permits intubation of the trachea and maintenance of anesthesia by use of inhalant anesthetics. The average dose of pentobarbital for induction of anesthesia is about 24 mg/kg, with a range of 11–54 mg/kg. In the lamb, the IV dose of pentobarbital ranges from 15 to 26 mg/kg; this usually maintains anesthesia for 15 minutes. An additional 5.5 mg/kg administered intravenously extends anesthesia a further 30 minutes. Recovery from anesthesia is rapid. Short et al. (1985) reported that an IV dose of 14.3 mg/kg pentobarbital produces anesthesia in sheep for about 5.39 ± 7.5 minutes; this time was from induction to return of the palpebral reflex.

RABBITS. Rabbits are considered to be one of the more difficult and unpredictable species of laboratory animals to anesthetize because they vary considerably in response to commonly used anesthetic agents, and the margin between surgical anesthesia and respiratory arrest is narrow (Murdock 1969). According to Murdock, the recommended IV dose of pentobarbital is generally 25–40 mg/kg. One-half to three-fourths of the calculated dose of 2% pentobarbital is injected slowly into the marginal ear vein until the animal becomes relaxed. Injection of more concentrated solutions is apt not only to lead to an overdose of the anesthetic but to cause severe injury to the vessel wall to the extent that thrombosis occurs. If this happens, vessel occlusion results, which will ultimately lead to necrosis and sloughing of the affected portion of the ear. Recovery from pentobarbital anesthesia is erratic in the rabbit, varying from 1 to 10 hours.

MINK. IV injection is not practical in vicious animals. Pentobarbital (22 mg/kg), injected subcutaneously, has been reported to produce a hypnosis suitable for examining mink and for artificial insemination procedures. The hypnotic state occurs in about 10 minutes and lasts for about 40 minutes, with complete recovery in about 1.5 hours.

Pentobarbital (35 or 40 mg/kg) has been used intraperitoneally in ranch mink (*Mustela vison*) without mortality (Graham et al. 1967). The use of diazepam, a neuroleptic agent, may be beneficial in mink prior to administration of anesthetics. Diazepam has been of value in calming aggressive and vicious animals prior to mating.

BIRDS. According to a number of literature sources, pentobarbital administered alone and intravenously has not been satisfactory as an anesthetic for the chicken because of the narrow margin of safety. The dose of pentobarbital varies greatly in chickens of the same strain, age, sex, and weight. Dose levels fatal for some birds produce only light anesthesia in others.

Pentobarbital readily depresses respiration or may paralyze respiratory activity of the chicken. However, it has been the experience of investigator, R. A. Herin, that pentobarbital (15 mg/kg) administered through the external thoracic vein provides safe anesthesia when oxygen is continuously administered to prevent hypoxia. Pentobarbital has been used in mature chicken hens for induction of light narcosis prior to inhalation of ether for maintenance anesthesia (Fussel 1969). The barbiturate is administered intraperitoneally in an average dose of 25 mg/kg; greater doses frequently produce respiratory and cardiac failure. Pentobarbital has a hypotensive action in fowl; soon after its administration there is a decline of 30–50 mm Hg in the arterial blood pressure, but this is followed by partial recovery in a few minutes.

Pentobarbital has also been satisfactorily used in the turkey by injecting 26 mg/kg via the radial or saphenous veins. It is recommended that birds be fasted 12–18 hours prior to anesthesia. Use of pentobarbital in the Aylesbury domestic duck by IV injection (30–60 mg/kg) produces unsatisfactory anesthesia (Desforges and Scott 1971).

An anticholinergic agent such as atropine sulfate (0.045 mg/kg intramuscularly) should be administered prior to use of barbiturates in birds to prevent bronchial secretion. Pentobarbital (1%) has been administered intramuscularly at a dose level of 0.01 mL (0.1 mg)/2 g to canaries, sparrows, parakeets, and chickens. Induction of anesthesia occurs in about 2 minutes; 5–9 minutes following the injection there is no skeletal muscle resistance to extension of the extremities. Surgical anesthesia lasts for approximately 30 minutes; the birds stand within 90 minutes after the injection.

Pentobarbital has been used for anesthesia in the Adelie penguin (*Pygoscelis adeliae*) (Andrews 1975). A dose of 50 mg/kg is recommended intraperitoneally for deep surgical anesthesia if it is a nonsurvival procedure. Induction of anesthesia is slow in the penguin, requiring an average time of 130 minutes. Up to 45% of body weight of the penguin consists of adipose tissue. What effect this may have upon anesthetic absorption and distribution is unclear. In addition, barbiturates appear to be metabolized very slowly in the penguin (Andrews 1975).

NONHUMAN PRIMATES. With introduction of ultrashort-acting barbiturates (thiopental, thiamylal), use of pentobarbital in primates has declined; however, pentobarbital is essentially safe and effective in monkeys. In the rhesus monkey (*Macaca mulatta*) most anesthetic failures in healthy animals following pentobarbital administration are attributable to an excessively rapid rate of injection or use of a highly concentrated solution (Domino et al. 1969). The commercially available pentobarbital solution containing 60 mg/mL is too concentrated and should be diluted 1:2 or 1:4 just prior to use. Moreover, the solution must be injected by slow, steady infusion at a rate not to exceed 2 mL/min until the corneal reflexes are abolished and respiration becomes slow, deep, and regular. Monkeys so treated can be expected to remain in surgical anesthesia for a minimum of 2 hours; recovery ordinarily does not occur in less than 6 hours (Domino et al. 1969).

Pentobarbital has been very useful as a restraint and anesthetic agent in the chimpanzee (*Pan troglodytes*) (Day 1965). The dose of pentobarbital recommended for mature and young chimpanzees is 24–29 mg/kg and 29–40 mg/kg respectively. A 5% pentobarbital solution is used in both age groups. Anesthesia occurs in most instances in 6–15 minutes. Complete recovery usually results within 6–8 hours, with the younger animals recovering in less time.

GUINEA PIGS AND GERBILS. Although the usual intravascular routes (IV and intracardiac) for administering anesthetics are available in the guinea pig, they are infrequently used (Hoar 1969); the intraperitoneal route is most common because of its easy and ready accessibility. A number of literature sources indicate that the anesthetic level for pentobarbital is 15–30 mg/kg administered intraperitoneally. However, an intraperitoneal dose of pentobarbital as high as 50 mg/kg is used in guinea pigs (McKay and Clement 1977). A heated operating board is recommended to prevent the severe hypothermia that occurs following this dose.

In the gerbil, pentobarbital in a dose of 5 mg/100 g (50 mg/kg) is recommended intraperitoneally (Stunkard and Miller 1974).

RATS AND MICE. Pentobarbital diluted in sterile physiologic saline solution is usually given intraperitoneally at a dose of 30–40 mg/kg to the adult albino male rat (Ben et al. 1969). However, Sprague-Dawley rats, both male and female, weighing 300–350 g are anesthetized with 60 mg/kg of pentobarbital intraperitoneally (Kawabori 1979).

Female rats are usually less capable of metabolizing pentobarbital and may require less than the male. Pentobarbital may be administered by the IV route in the rat; however, the dose level and rate of administration must be carefully observed (Ben et al. 1969). In mice, pentobarbital is the most commonly used parenteral anesthetic agent and is generally given intravenously or intraperitoneally in doses of 40–70 mg/kg (Taber and Irwin 1969). Intraperitoneally, this dose range induces anesthesia of 20–30 minutes following a latency interval of 5–10 minutes with less than 10% mortality. Literature sources indicate that male mice are more sensitive to the effect of barbiturates than females. In the neonatal subject (1–4 days old), an intraperitoneal dose of 5 mg/kg pentobarbital produces anesthesia of approximately 1 hour (Taber and Irwin 1969).

AMPHIBIANS AND REPTILES. Frogs (*Rana pipiens*) can be satisfactorily anesthetized with pentobarbital administered through the dorsal lymph sac at a dose of 60 mg/kg (Kaplan 1969). Surgical anesthesia is attained in about 0.5 hour and will last for as long as 9 hours. Turtles (*Pseudemys*) can also be anesthetized with pentobarbital by IV or intracardiac injection at a dose level of 15.5–17.5 mg/kg. Induction time of anesthesia is approximately 30–53 minutes by these routes; the animals may remain in deep anesthesia as long as 3 hours. Turtles may also be anesthetized by the intraperitoneal route with pentobarbital at a dose of 16 mg/kg (Kaplan 1969).

BEARS AND LARGE CATS. Pentobarbital has been used intravenously (37–59 mg/kg) in bears following IM administration of morphine sulfate (8.8 mg/kg) and promazine (4.4 mg/kg). For safe handling and minor surgery, a mean IV dose of 13.5 mg/kg pentobarbital is recommended in bears; supplemental increments will maintain the animals in anesthesia for up to 6 hours. The principal disadvantage in using pentobarbital in bears is the necessity for immobilizing them so that a venipuncture can be made; once this is achieved, pentobarbital (12–15 mg/kg) is administered as rapidly as possible (Day 1965). This is about 50–75% of the anesthetizing dose. The remaining portion is then given until an adequate level of anesthesia is reached.

Pentobarbital is contraindicated in any of the large zoo cats because of their apparent inability to metabolize it. Large cats may be anesthetized for 6 or 7 days following use of pentobarbital. When ultrashort-acting barbiturates (thiamylal or thiopental) are administered, these animals sleep 6–24 hours.

Thiopental Sodium. As the name indicates, *Thiopental Sodium*, USP (Pentothal sodium, Intraval sodium, Thiopentone sodium), is a sulfur-containing barbiturate or a thiobarbiturate. Instead of having the *R*-O-Na characteristic of most other sodium salts of the barbituric acid derivatives, thiopental possesses a sulfur atom, *R*-S-Na, in substitution for the oxygen atom. Except for the sulfur atom, thiopental is similar chemically to pentobarbital (see Fig. 12.4). Thiopental is classified as a Schedule III drug under the 1970 Controlled Substances Act.

Thiopental is a weak organic acid with a pK_a value of 7.6; it has a relatively low ionization (39%) at the pH of plasma (Brandon and Baggot 1981). High lipid solubility of the nonionizing moiety is the primary property of this anesthetic agent, permitting it to quickly penetrate the blood-brain barrier.

STORAGE AND STABILITY. Thiopental is available in sealed, evacuated or nitrogen-filled ampules as a powder buffered with sodium carbonate and should be stored away from light in a cool place. It is unstable in aqueous solution or when exposed to moisture. Steady deterioration occurs in proportion to the temperature of the solution. For maximum effect and safety, aqueous solutions of thiopental should be prepared just prior to use. When large amounts are used, as in a hospital, a bulk solution of thiopental may be prepared if careful attention is given to its expiration date. A 5% bulk solution can be stored in a refrigerator at 5–6°C until turbidity appears, but for no longer than 7 days. At room temperature at 18–22°C a solution should be kept no longer than 3 days. Solutions kept beyond these limits contain clinically active thiopental, but the progressive loss of action at any given period cannot be easily determined. When aged solutions are used, the same characteristic action of the drug is obtained by injecting larger volumes of solution. However, from the standpoint of maintaining a reliable anesthetic and surgical routine, it is desirable to use fully potent, fresh solutions.

PHARMACOLOGIC CONSIDERATIONS. Thiopental is not ordinarily associated with excitatory side effects and, even when administered in dosages sufficient to induce an isoelectric electroencephalogram (EEG), has no ostensible direct toxic effect on the CNS (Steen and Michenfelder 1979). In the dog, large doses have been given to produce an isoelectric EEG for 30 minutes or longer. Under these conditions, cerebral oxygen consumption is about 40% of normal; brain energy stores, i.e., adenosine triphosphate and phosphocreatine, are normal throughout this period as well as the concentration of brain lactate. Such findings in dogs are consistent with the clinical experience with barbiturate intoxication in humans. If respiratory and circulatory supports are instituted early enough and adequately maintained in reversal of the intoxication, cerebral recovery is expected even when EEG activity is initially absent (Steen and Michenfelder 1979).

In the horse, thiopental elevates the blood glucose level and induces a leukopenia. The cardiac rate increases, while cardiac output decreases. No significant change in arterial pressure or packed cell volume occurs in the horse following administration of thiopental. Respiration is slowed and frequently becomes irregular for brief periods. This leads to an elevated arterial P_{CO_2} and concomitant decrease in blood pH. Plasma levels of thiopental do not correlate well with the clinical signs or EEG in the horse or other species.

Middleton et al. (1982) reported that 60% of the cats in a study developed apnea that lasted over 50 seconds after the beginning of an IV injection of 1.25% thiopental (20 mg/kg) at a rate of 0.5 mL/sec. Also, a mild arterial hypotension occurs between 5 and 10 minutes after injection.

In Greyhound dogs (22–25 kg), IV administration of 2.5% thiopental (10 mg/kg) reduces systemic arterial pressure about 40% immediately after injection (Smith et al. 1982). However, the pressure returns to near normal within 5 minutes after injection.

In the dog, thiopental has an arrhythmogenic effect with an incidence of about 40%. This is lower than the incidence (i.e., 85%) of arrhythmia produced in the dog by thiamylal (Pedersoli and Brown 1973).

IV thiopental-induced (20 mg/kg) anesthesia potentiates development of ventricular arrhythmia when epinephrine is administered to halothane-anesthetized dogs (Atlee and Malkinson 1982). This potentiation may last for at least 4 hours after the thiopental-induced anesthesia (Bednarski et al. 1985).

Anesthetics such as the ultrashort-acting barbiturates (thiopental, thiamylal, methohexital)that trigger cardiac arrhythmias set the stage for the heart to go into ventricular fibrillation, especially if endogenous or exogenous catecholamines appear at the right time.

Compared to IV thiopental (22 mg/kg) alone in the dog, the IV combination of thiopental (11 mg/kg) and lidocaine (8.8 mg/kg) induces no arrhythmia and produces less cardiopulmonary depression (Rawlings and Kolata 1983). Bigeminy, with alternating premature ventricular depolarization and normal sinus-initiated depolarizations, occurred after intubation of the trachea during 19 of 20 thiopental inductions; the bigeminies were preceded by tachycardia and an increase in arterial pressure during tracheal intubation. In contrast, 20 dogs given the thiopental-lidocaine combination did not develop cardiac arrhythmia. According to Rawlings and Kolata (1983), the thiopental-lidocaine combination would appear to be a good method of inducing anesthesia in animals with cardiopulmonary disease because it elicits less cardiopulmonary depressive effects and protects against arrhythmia.

Between 30 and 60 minutes of IV thiopental anesthesia (25 mg/kg) in the dog, there is a slight decrease in cardiac output and left ventricular work (Ahlgren et al. 1978). Blood flow is reduced to the lungs, kidneys, and liver. Between 60 and 90 minutes following administration of thiopental, a steady state in cardiovascular function is essentially attained. Only blood flow to the liver remains below normal.

METABOLISM AND DISTRIBUTION. Thiopental is metabolized primarily by the hepatic microsomal enzyme system. Studies in the monkey with thiopental containing labeled sulfur, S^{35}, indicate that at least 12 metabolic products are excreted in urine. Within 4 days after an IV injection of 35 mg/kg, the monkey excretes about 86% of the dose in urine. Additional small amounts are found in feces and tissues.

In humans, only about 0.3% of administered thiopental is excreted unchanged, indicating that the drug is almost totally transformed. Oxidation of one of the alkyl side chains yields thiopental carboxylic acid, a metabolite of thiopental, which is almost completely metabolized; only traces of this metabolite appear in urine. The metabolite has little if any anesthetic activity. In chronic renal failure patients (human), the rate of thiopental elimination is much the same as in normal individuals (Burch and Stanski 1982).

In clinical anesthesia a small dose of thiopental has a brief duration of action, not because of its rapid metabolic destruction but because of rapid distribution of the drug from plasma into the adipose tissues. Actually, the metabolic conversion of thiopental is slow (10–15%/hr). Since fat is capable of localizing thiopental, the plasma level of the anesthetic is below that required to maintain anesthesia, and the animal recovers soon after injection. Following large doses or repeated small doses of thiopental, the plasma level remains near that of the fat and tissues, and anesthesia persists for a longer period because of slow metabolism of the anesthetic.

Use of a thiobarbiturate such as thiopental in maintenance of anesthesia is not condoned (Dodman et al. 1984). Its continuous use in maintenance of anesthesia will result in prolonged and unfavorable recovery.

Since recovery depends on redistribution of thiopental from the brain to other tissues, animals that are severely cachexic will have prolonged recoveries.

In sheep, thiopental is cleared from plasma at the rate of 17%/hr after tissue equilibrium is reached. The half-life of thiopental in sheep (herbivore) is about one-half that of the carnivore (Baggot et al. 1984). Pentobarbital is cleared at a rate of approximately 49%/hr in sheep. Binding of the two barbiturates to sheep plasma proteins occurs to the extent of 67% for thiopental and 36% for pentobarbital. Only free (unbound) thiopental is able to cross the blood-brain barrier.

The phenomenon of microsomal enzyme induction has been demonstrated in calves pretreated with phenobarbital (Sharma et al. 1970). Plasma levels of thiopental are reduced at a more rapid rate as a result of enzyme induction. The development of enzyme induction should be considered while treating domestic animals because they are frequently exposed to potent inducers of microsomal enzymes such as halogenated pesticides and other compounds. Such induction may be responsible for wide variation in metabolism of certain drugs and may greatly affect an animal's response (Sharma et al. 1970).

PHARMACOKINETICS. After IV injection of thiopental (20 mg/kg) in a concentration of 2%, the apparent volume of distribution in sheep is 1005 ± 196 mL/kg (Toutain et al. 1983). Its body clearance is 3.5 ± 0.8 mL/kg/min and the plasma half-life is 196 ± 64 minutes.

In the dog, IV administrations of 2.5% thiopental results in a plasma half-life of 6.99 ± 2.18 hours, an apparent volume of distribution of 843 ± 194 mL/kg and a body clearance value of 1.51 ± 0.60 mL/kg/min (Brandon and Baggot 1981). The plasma half-life of thiopental in the dog is about 5–6 times longer than in sheep. According to Brandon and Baggot, the relatively short duration of thiopental anesthesia in sheep may be attributed primarily to biotransformation of the drug by hepatic metabolism and uptake by body fat.

Pharmacokinetic studies of thiopental have been made possible by development of a highly sensitive, rapid reverse phase, high-pressure liquid chromatographic (HPLC) method (Christensen and Andreasen 1979). The detection limit of thiopental in blood by HPLC is 90 ng/mL, or 90 ppb.

TOXICITY. The major toxic effect of thiopental is a marked depression of the respiratory centers; the rate is slowed and amplitude decreased. Ordinarily, the respiratory rate is a good indication of the condition of the animal and the dosage of drug. When given properly, thiopental has little toxic action upon the cardiovascular system, about 16 times as much is needed to stop the myocardium as to paralyze respiration. As long as the cardiovascular system functions well, there is every opportunity for recovery of a patient if proper oxygenation is maintained by artificial respiration.

An apparent lethal anaphylactic response to thiopental has been reported in the dog (Mason 1976). The reaction developed 10 days following a second administration in a 4-year-old Border Collie. Acepromazine and atropine premedication in conjunction with β-irradiation therapy as well as a corticosteroid were used during thiopental anesthesia. A survey of the veterinary medical literature failed to locate any evidence of anaphylactic reaction to thiopental. Anecdotal evidence suggests equine patients may occasionally develop urticaria after thiopental administration. In humans, an anaphylactic reaction to repeated administration of thiopental is recognized as a rare entity. Painful vesicular lesions (mouth, skin), referred to as fixed-drug eruptions, have been reported in the human several hours after conclusion of thiopental anesthesia (Butler et al. 1982).

In general, thiopental possesses a wide margin of safety. The twice daily injection of 20 mg/kg into dogs for 2–3 weeks results in only slight depression of liver function.

GENERAL USE. The brief duration of effect of thiobarbiturates can be employed advantageously for numerous conditions, including setting fractures; gynecologic, radiographic, and other kinds of examinations; short surgical procedures; and premedication to an inhalant anesthetic. The rapid, complete recovery permits quick return of the patient to the owner if hospitalization is undesirable. The minimal hypnotic dose of thiopental injected intravenously produces anesthesia for only about one-fourth as long as pentobarbital under the same conditions.

During World War II, thiopental came into wide use as a routine anesthetic in humans in front-line hospitals where equipment was limited.

ADMINISTRATION AND DOSAGE. Thiopental is administered only by IV injection. Subcutaneous or IM injections are irritating and may result in sloughing of tissue. The anesthetic is too irritant to inject into a body cavity. An equal volume of 1% procaine infiltrated into the perivascular tissue where the thiopental may have been injected by accident is claimed to obviate the usual tissue reaction. Thiopental is usually prepared as a 2.5% solution for IV injection in smaller animals. In larger animals the concentration should be increased to 5%, although 10% solutions have been used. It should be borne in mind that injection of the more concentrated solution (5 or 10%) will produce serious complications if the barbiturate anesthetic is accidentally administered intra-arterially. The "quick-shot" administration of thiopental in the horse via the external jugular vein may result in inadvertent injection of the anesthetic extravascularly. This often results in severe tissue reaction, including abscessation and necrosis of the involved tissue (Jones 1968). If thiopental is accidentally injected perivascularly, normal saline should be injected to dilute the drug; in addition, hyaluronidase should be added to normal saline to promote dispersion and absorption of the thiopental (Jones 1968).

The amount of thiopental needed varies with the disposition of the patient and the nature of the operation. Of the several factors seeming to influence depth and duration of anesthesia, the most important is rate of injection. When small animals are injected rapidly (i.e., within 0.5 min), onset of anesthesia is abrupt and sometimes alarming. It must not be forgotten that too rapid IV injection depresses the vasomotor center and results in a vascular dilation with sudden drop in blood pressure.

Rapid injection usually induces anesthesia in less than a minute and lowers the dosage needed, but the anesthesia is of brief duration. Duration is directly proportional to the time taken for injection of the anesthetic dose. The duration can vary from 2–3 minutes to 25–30 minutes, depending on the rate and amount of drug injected. At either extreme, the same depth of depression can be produced. Repeated injection of thiopental is not advised; recovery is prolonged with each additional dose administered. Barbiturate anesthesia in the horse should not be maintained for long periods; no more than a total of 5 g of any barbiturate should be administered intravenously even to horses of draft proportions (Heath 1977).

In the dog, the anesthetic IV dose of thiopental approximates 15–17 mg/kg; for the cat it is 9–11 mg/kg (Mark et al. 1968) up to 20 mg/kg (Middleton et al. 1982). However, each dose should be adjusted to the patient to compensate for individual differences. Regardless of the dose, the initial injection of a solution of thiopental in small animals should consist of about 13 mg/kg followed by a pause of 30–60 seconds. The remainder of the desired dose can be injected to effect during the next 1–2 minutes.

For brief anesthesia of 7–10 minutes (suitable for radiography, minor surgery, and examinations) a dose of 13–18 mg/kg is suggested. In myelography it is advisable to avoid use of barbiturates; sodium methiodal, a contrast medium, may displace bound thiopental and induce anesthetic complications (Bonhaus et al. 1981). For anesthesia of 10–15 minutes, as might be needed for reducing a fracture, a dose of 18–22 mg/kg is desirable. For anesthesia of 15–25 minutes to permit major surgery, a dose of 22–29 mg/kg is needed in most small animals. Thiopental is not recommended for extended periods of anesthesia. It may be used to induce anesthesia, followed then by safer agents such as inhalant anesthetics for prolonged effect. A small dose of thiopental injected rapidly produces anesthesia briefly.

If desired, morphine can be administered preanesthetically to thiopental as it is to pentobarbital. However, morphine does not cause a significant extension of thiopental-induced anesthesia in the dog. Prolongation by a therapeutic dose of the narcotic analgesics appears to be less significant than that observed with most of the phenothiazine tranquilizers. Atropine sulfate or glycopyrrolate should be routinely used preceding thiopental anesthesia to prevent parasympathetic side effects. Atropine sulfate, but not atropine methylnitrate, nonspecifically reduces the anesthetic dosage of thiopental plasma level at awakening (Hatch 1972).

RECOVERY. The recovery period varies with dosage from 15 minutes to 6–8 hours before full leg coordination appears and may not be complete in less than 24 hours in the dog following an IV dose (15–25 mg/kg) of thiopental (Chenoweth and Van Dyke 1969). With repeated administration of the drug, recovery time is prolonged to the extent that there is little advantage over the use of pentobarbital. According to Hatch (1966), rapid administration of glucose in the dog that is regaining voluntary movement from thiopental anesthesia results in reanesthetization of 11% of the animals. Sodium lactate and epinephrine also produce an increase in the sleep time. However, the possibility of producing reanesthetization with these substances is of little practical concern as long as they are administered properly.

Old animals may exhibit hindleg weakness for 1–2 days after thiopental anesthesia. Incoordination of the legs, especially the rear legs, causes the patient to stagger about for an hour or so when disturbed during recovery. If the patient is not disturbed, recovery ordinarily is uneventful. Complete recovery requires approximately 2 hours and is usually free from excitement. Vomiting or other signs of postanesthetic toxicity have seldom been noted.

RESUSCITATION. As with other barbiturates, excessive amounts of thiopental produce severe respiratory depression. Continuous administration of oxygen and artificial ventilation is more beneficial than any other therapeutic measure for combating the respiratory depression from barbiturate overdosage.

CLINICAL USE. Thiopental is approved by the FDA for use in the dog, cat, bovine, sheep, and swine.

SMALL ANIMALS. Anesthesia produced by thiopental in small animals is very similar to that by pentobarbital. Although muscular relaxation is fair, it is inferior to that produced by ether and other inhalant anesthetics. Respiration is regular but slow and shallow. The heart beat is fast but strong. Excitement is generally absent during induction and recovery if the patient is kept quiet. IV thiopental (10 mg/kg) is used for induction of anesthesia in the dog premedicated with atropine to permit endotracheal intubation for administration of an inhalant anesthetic (Cribb et al. 1977).

The anesthetic dose of thiopental for the dog is 15–20 mg/kg administered by the IV route; for the cat it is 9–11 mg/kg (Robinson et al. 1986; Sams et al. 1985; Turner and Ilkiw 1990; Quandt and Robinson 1992; Mark et al. 1968). These doses are generally considered to be on the conservative side; e.g., some authors recommend an IV dose of 25–30 mg/kg thiopental for both the dog and cat (Mitchell 1966; Strobel and Wollman 1969). Strobel and Wollman reported that 30 mg/kg of the drug will produce 10–20 minutes of anesthesia and 2 hours of somnolence. The use of preanesthetic agents such as xylaxine or acepromazine will reduce the dose of thiopental required to produce anesthesia (Ko et al. 1993; Hatch et al. 1985; Hatch 1972; Hatch 1973c). In the Greyhound, compared to other breeds of dogs, the recovery rate from thiopental anesthesia is more prolonged. The Greyhound can metabolize methohexital, an ultrashort-acting oxybarbiturate, much more rapidly than the thiobarbiturate anesthetics.

Doses of 12 and 24 mg/kg thiopental administered intravenously in the cat require 27 ± 8 minutes and 63 ± 6 minutes after the barbiturate is injected before recovery of the righting reflex (Child et al. 1972a). Because of considerable variability in the anesthetic dose level for the dog and cat, thiopental should be administered cautiously and to effect. In the cat, administration of increasing amounts of thiopental does not allow EEG patterns to be related to the clinical depth of anesthesia or plasma thiopental concentration (Hatch et al. 1970).

SWINE. Thiopental in 5% IV solution has been used satisfactorily in swine varying in weight from 4.5 to 270 kg. Although dose levels of thiopental generally used in clinical practice can differ considerably from those recommended by Muhrer (1950), the information is nevertheless useful for determining the initial amount of drug needed for induction (Table 12.4). Swine weighing 5–50 kg usually require doses of 10–11 mg/kg (Booth 1969). In pregnant sows weighing 165–323 kg, induction of anesthesia without premedication is accomplished by IV injection of thiopental (2.5–6.25 g) to effect; no reliable dose/weight relationship is observed (Cummings et al. 1972). After endotracheal intubation, a gas mixture of oxygen and nitrous oxide in a ratio of 1:1 or 1:2 can be delivered to the animal.

About 1 hour is required before swine can move about satisfactorily after thiopental administration. This period is ordinarily longer than in humans, dogs, rabbits, and some other animals where approximately 15 minutes are usually required for recovery. In general, swine show a slower recovery rate from the effects of any CNS depressant than other species. The obese condition of swine is apparently contributory to a slower recovery period because thiopental is known for its ability to localize in fat.

Hemorrhage or blood loss of 30% in the pig decreases the anesthetic induction dose of thiopental by

TABLE 12.4—Suggested IV dose of thiopental sodium in swine

Weight	Dose	Dose in 5% solution
(kg)	*(mg/kg)*	*(ml/kg)*
4.5–22.7	11.0	0.22
22.7–45.4	9.9	0.19
45.4–90.9	8.8	0.17
90.9–136.3	7.7	0.15
136.3–181.8	6.6	0.13
181.8–272.7	5.5	0.11

Note: Unthrifty animals require less drug for a comparable effect.

33% (Weiskopf and Bogetz 1985). The resulting hypovolemia may alter the degree of binding of thiopental to serum albumin. Consequently, the presence of hypoproteinemia that accompanies blood loss and hypovolemia would mean that less anesthetic is bound to serum albumin. Thus the anesthetic effect may possibly increase due to less bound or more free circulating thiopental after hemorrhage.

Thiopental is best given intravenously via the cranial vena cava by an indwelling catheter (Booth 1969). Since respiratory depression readily occurs in swine, endotracheal intubation is necessary for oxygen administration and/or artificial respiration. In addition, intubation of the pig provides an excellent means for supplementing thiopental with inhalant anesthetics.

CATTLE. IV thiopental has been used to produce surgical anesthesia for laparotomy in calves under 2 weeks. A 6.5% solution (65 mg/mL) should be injected slowly during 4–5 minutes until complete muscular relaxation occurs. The total dose varies from 15 to 22 mg/kg. The stage of light surgical anesthesia usually lasts for 10–12 minutes. Partial recovery follows rapidly, with complete recovery of limb coordination in 2 hours. A transient stage of deep hypnosis or light surgical anesthesia results from rapid injection of a small dose of thiopental; 6.6 mg/kg injected intravenously within 10 seconds produces deep hypnosis in 270–360 kg steers. The full effect is apparent within 1–2 minutes and persists 5–10 minutes. Steers fall to the ground soon after the rapid injection and assume a normal recumbent position in about 0.5 hour and stand within 2–3 hours. The phlegmatic disposition of the bovine ordinarily results in quiet recovery and only slight incoordination when the animals stand. Thiopental (0.2%) and guaifenesin (5%) in 5% glucose is used intravenously (2.2 mL/kg) in Angus and Hereford bulls for induction of anesthesia (Garner et al. 1975). This is followed with halothane-oxygen for maintenance of anesthesia.

HORSES. Rapid IV injection of thiopental without benefit of preanesthetic agents or tranquilizers has been tried in horses. While anesthesia may occur briefly, the recovery period in the horse is so marked by excitement and incoordination that use of thiopental alone is contraindicated. Adverse effects may arise partly from action of the drug, but much of the difficulty undoubtedly results from the nervous and excitable disposition of the horse in comparison to the phlegmatic disposition of the bovine.

Frankland and Camburn (1977) have used IV xylazine hydrochloride (0.22 mg/kg) 10–15 minutes prior to induction of anesthesia with 10% IV thiopental (1 g/90 kg given evenly over 20 seconds). They have also used IV acepromazine (0.05 mg/kg) 15 minutes prior to thiopental induction or 30 minutes prior to induction of anesthesia when acepromazine is administered intramuscularly. The mean induction time of anesthesia following xylazine and acepromazine is 28.2 and 14.6 seconds respectively. Although induction time of anesthesia is shorter following acepromazine, xylazine usually provides a greater degree of tranquilization (Frankland and Camburn 1977). However, both these regimens are satisfactory clinically. According to Frankland and Camburn, it is still a matter of personal preference which of these preanesthetics is used.

Clinical experience with thiopental (10%) in the horse indicates that the rapid IV injection of a dose (10 mg/kg) that will induce anesthesia is accompanied by a moderate tachycardia, a slight reduction in arterial pressure, and a brief period of apnea lasting from 0.5 to more than 1 minute (Tavernor and Lees 1970). In addition, a transient reversal in the T wave of the electrocardiogram (ECG) is seen in some animals. Thiopental is considered to be relatively safe for anesthesia in the horse, providing the rate and character of respiration are carefully observed. It is often used intravenously for rapid ("crash" or "quick-shot") induction of anesthesia in the horse at the rate of 6.6 mg/kg in a tranquilized animal (Short 1974; Short and Brunson 1978). Without tranquilization, the dose of thiopental required to induce anesthesia may increase as much as 25%. Induction of anesthesia usually requires 0.5–1 minute after injection of the drug and corresponds to the speed or rate of injection of the anesthetic agent. A more gradual approach to induction of anesthesia may be preferred by use of thiopental in combination with guaifenesin. Three grams of thiopental are added to 1 liter of 5% guaifenesin. This mixture is rapidly administered through a 12-gauge IV catheter. Recumbency occurs after approximately 1 mL/kg has been administered. Additionally, an IV bolus of 2–4 mg/kg of thiopental can be administered when limb weakness is noted to speed induction and decrease the amount of guaifenesin-thiopental mixture needed. Premedication with xylazine (0.5–1.0 mg/kg IV) or acepromazine (0.03–0.06 mg/kg IV) is recommended (Benson and Thurmon 1990).

GOATS. Thiopental (5%) has been satisfactorily used in the goat for surgical procedures lasting about 2 hours. Since the animal detoxifies the anesthetic at a rapid rate, the dose required for anesthesia varies greatly. An initial IV dose of 20–22 mg/kg is usually effective in anesthetizing the goat.

Atropine is capable of controlling salivation in the goat following barbiturate anesthesia. However, larger preanesthetic IM doses (0.7 mg/kg) are required than customarily used in other species. To maintain control of salivation during surgical anesthesia, it is necessary to repeat the atropine, administered by the IV route, at 15-minute intervals at a dose of 0.1–0.2 mg/kg.

An endotracheal catheter is routinely used to protect the airway from possible regurgitated ruminal contents. Tracheal intubation is valuable for administration of oxygen in the event of respiratory depression or arrest from an overdose of anesthesia.

BIRDS. Thiopental is administered intravenously via the wing vein to geese, ducks, chickens, and pigeons for induction of anesthesia. Anesthetic doses are 13–22 mg/kg for native Chinese geese, 18–26 mg/kg for ducks, and 13–18 mg/kg for chickens and pigeons. Sudden death often occurs in pigeons during administration of the anesthetic. In the chicken, injection of 13 mg/kg of thiopental is without satisfactory results, and death occurs if the dose exceeds 18 mg/kg. The relative lack of safety and short duration of anesthesia make this agent unsatisfactory for poultry surgery.

NONHUMAN PRIMATES. When short-term surgical procedures are indicated and rapid recovery is preferred, thiopental is a useful anesthetic agent in nonhuman primates (Day 1965; Sawyer 1965a; Domino et al. 1969). In the chimpanzee, thiopental is the agent of choice for long-term (3–4 hr), light-stage anesthetic procedures and short-term (30–45 min) surgical procedures (Day 1965). According to Day, the initial dose of thiopental is 33 mg/kg, which produces light stage III anesthesia.

In the rhesus monkey, thiopental is administered intravenously at a dose level of 25–30 mg/kg (Sawyer 1965a; Domino et al. 1969). According to Sawyer, the excitatory phase during induction of anesthesia is not as turbulent as in the canine species, and the slow rate of administration of the barbiturate can be readily performed. This type of response during induction of anesthesia reduces the possibility of administering an overdose. Sawyer (1965a) advocates administration of atropine (0.04 mg/kg) prior to or at the time of anesthesia induction.

Duration of thiopental anesthesia from a single administration is not more than 10 minutes in the rhesus monkey, and recovery generally is complete within 45–60 minutes (Domino et al. 1969).

RABBITS. Thiopental (2.5%) is used as the IV anesthetic of choice in the rabbit (Sawyer 1965b). Sawyer recommends slow administration via the ear vein while the respiratory rate and oral and palpebral reflexes are observed. He also emphasizes that the pedal reflex should not be used to determine depth of anesthesia; when this reflex is severely depressed or absent, animals may be in the terminal stage of anesthesia. The IV dose level of thiopental recommended for the rabbit ranges from 30 to 50 mg/kg; this will produce anesthesia varying from 5 to 20 minutes. Full recovery usually occurs within 15 minutes (Murdock 1969; Wood 1978).

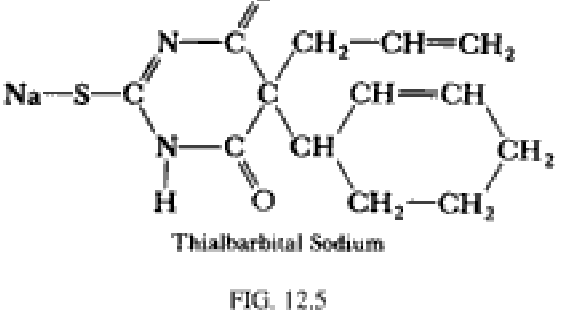
SNAKES. Experimentally, skin grafting procedures have been conducted in bull snakes (*Pituophis catenifer*) and Texas rat snakes (*Elaphe quadrivittata*) using thiopental and thiamylal 2–6 mg/kg intraperitoneally for induction of surgical anesthesia (Kraner et al. 1965). It is necessary to administer both in dosages near the lethal level to be effective. Moreover, recovery is observed to be extremely slow, taking 48–72 hours even when analeptic agents are used (Kraner et al. 1965). A large number of snakes fail to survive barbiturate-induced anesthesia. For this reason, Kraner et al. (1965) found the use of inhalant anesthetics more satisfactory than thiopental or thiamylal.

KANGAROOS. Small kangaroos (tammar, wallaby, quokka) are often anesthetized up to 2–3 hours for therapeutic or research purposes (Richardson and Cullen 1981). Thiopental (2.5%) given in an IV dose of 28.4 ± 6.2 mg/kg for wallabies and 27.8 mg/kg for quokkas provides an unconscious state satisfactory for tracheal intubation and maintenance with halothane.

Thialbarbital Sodium. *Thialbarbital Sodium,* INN (Thialbarbitone sodium), is a sulfur-containing barbiturate (Fig. 12.5). Its duration of action is intermediate between the short-acting and ultrashort-acting barbiturates. Thialbarbital has a potency of approximately one-half that of thiopental and has similar pharmacologic characteristics. It is classified as a Schedule III compound under the 1970 Controlled Substances Act.

CHEMISTRY. This compound is a sodium salt of 5-(2-cyclohexen-1-yl)-5-allyl-2-thiobarbituric acid. Thialbarbital is used in about a 10% buffered aqueous solution. Unbuffered solutions have a pH of 10.6. Thialbarbital is almost entirely detoxified by body tissues.

Thiamylal Sodium. *Thiamylal Sodium,* USP, is an ultrashort-acting thiobarbiturate (see Fig. 12.6) prepared for use in a mixture with sodium carbonate, a buffering agent. It consists of pale yellow, hygroscopic



Thialbarbital Sodium

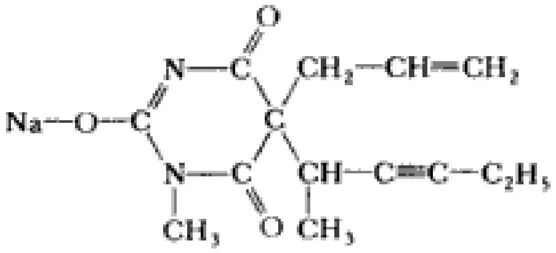
FIG. 12.6



Methohexital Sodium

FIG. 12.7

masses of crystals. Thiamylal is classified as a Schedule III compound under the 1970 Controlled Substances Act. Thiamylal is not currently produced in the USA, although it was widely used when available.

Chemistry. Thiamylal is the thiobarbiturate analog of secobarbital. It is freely soluble in water, with a pH of about 10.5. The solution is clear, bright, and yellow, with a pungent odor; the pH decreases slowly when carbon dioxide is absorbed from the atmosphere. Air should not be bubbled through the solution during preparation. It should be discarded if a precipitate forms.

Stability. Thiamylal is relatively stable as a dry powder mixed with sodium carbonate and stored in airtight vials. Solutions of thiamylal cannot be subjected to heat or sterilization because of deterioration. Refrigeration or storage in a cool, dark place is necessary once the preparation is in the form of a solution, and it should be used within 24 hours.

Clinical Use. The clinical use of thiamylal is very similar to that of thiopental. Thiamylal is slightly more potent than thiopental. This drug is discussed in greater detail in the 7th edition of this text.

Methohexital Sodium. Several hundred barbiturates have been synthesized in an effort to find an ultrashort-acting barbiturate with greater potency and shorter duration of action than the thiobarbiturates, viz., thiopental and thiamylal. As the result of this effort, an oxybarbiturate (methohexital sodium) was synthesized. *Methohexital Sodium*, USP (Brevane, Brietal, Brevital, Brevimytal), has been approved by the FDA for use only in the dog and cat. It is classified as a Schedule IV compound under the 1970 Controlled Substances Act.

Chemistry. Chemically, methohexital is α-*dl*-1-methyl-5-(1-methyl-2-pentynyl)-5-allyl-barbituric acid sodium (see Fig. 12.7). This anesthetic agent resembles secobarbital and pentobarbital, the oxygen analogs of thiamylal and thiopental respectively.

Methohexital, with a methyl group on an N atom, is more potent than thiopental but has a higher incidence of CNS excitatory effects. When the anesthetic was first introduced in clinical trials, convulsions were commonly encountered in humans (Steen and Michenfelder 1979). Upon separation of the compound into its isomers and identification of those responsible for CNS excitation, the convulsant properties of methohexital were greatly reduced. However, CNS excitation including convulsions remains a possibility following its use. The excitatory activity of methohexital has been used to advantage in clinical diagnostic investigations of petit mal and temporal lobe epilepsy in humans. Methohexital activates abnormal EEG tracings in epilepsy-prone subjects.

Stability. Methohexital is stable in an aqueous solution at room temperature for at least 6 weeks at a pH of 11. It is readily dissolved in saline or distilled water.

Administration. Methohexital is administered as a 1% solution in the dog and cat by the IV route. Perivascular injection does not produce tissue irritation. Rate of administration of methohexital plays an important role in depth and duration of anesthesia. It is recommended that the drug be injected as rapidly as possible, consistent with safety, to reach a suitable plane of anesthesia. The 1% solution is injected at approximately 1 mL/sec. If a slow injection rate is used, muscular tremors frequently occur. Similar findings, including CNS excitation, have been reported in humans.

When methohexital is injected rapidly, induction of anesthesia is smooth and rapid. Dogs and cats are able to lift their heads or can sit up within 5–10 minutes. Complete recovery occurs within 30 minutes. When IM promazine (3.3 mg/kg) is administered preceding methohexital by 1 hour, duration of methohexital anesthesia is slightly prolonged but recovery is smoother.

In the Greyhound, recovery from thiobarbiturate (thiopental or thiamylal) anesthesia is prolonged compared to mixed-breed dogs (Sams et al. 1985). Recovery is over 2–3 times as long after thiobarbiturate anesthesia as from methohexital anesthesia.

The effective IV dose of methohexital for induction of anesthesia in the Greyhound is 9–11 mg/kg. The recommended rate of injection is about 25 mg/sec (1 mL/sec of a 2.5% solution). Inadvertent extravascular injection of this concentration does not result in any untoward effects when left untreated as compared to a

5% solution of thiopental, which causes swelling, lameness, and even sloughing of tissues.

In humans, the anesthetic is considered to be an ideal preparation for rapid induction of hypnosis when inhalation anesthesia such as halothane is used. Since the drug is rapidly metabolized, it does not interfere with use of inhalant anesthetics.

TOXICITY. It has been observed in humans that respiratory depression is more severe following use of methohexital than with thiamylal or thiopental at a comparable level of narcosis (Taylor and Stoelting 1960). Inasmuch as respiratory depression is prevalent throughout the course of anesthesia in the human subject, it is necessary to assist respiration by artificial means. In humans, pain at the injection site occurs in 60% of the patients.

In the normal, healthy dog and cat at least twice the calculated dose of methohexital can be given with safety.

CONTRAINDICATIONS. Methohexital should not be used as an anesthetic in known or suspected cases of epilepsy in animals. Its use for anticonvulsant purposes in treatment of strychnine poisoning, tetanus, or other conditions associated with increased CNS excitation is inadvisable.

DOSAGE. Clifford and Soma (1969) recommend a dose of 5.7 mg/kg for the cat. This dose of methohexital is slightly less than that (i.e., 7.3 mg/kg) formerly recommended. For dogs weighing up to 13.6 kg, an IV dose of 7.3 mg/kg methohexital is recommended; for dogs over 13.6 kg, the IV dose is 5.5 mg/kg.

CLINICAL USE. Comparison of the potency of methohexital and thiopental for several species has indicated that methohexital is twice as potent as thiopental (Turner and Ilkiw 1990). Table 12.5 gives the median anesthetic doses and average durations of anesthesia in the dog, cat, and monkey.

Methohexital is used in the horse as a 2.5% solution at a dose of 5 mg/kg. The anesthetic preparation is injected intravenously at a rapid rate. The horse falls to the ground within 15–20 seconds, with the period of anesthesia not exceeding 5 minutes. This permits enough time to insert an endotracheal catheter so that inhalant anesthetics can be administered.

Methohexital should not be used alone because excitation during recovery limits its use in the horse (Grono 1966). Premedication with neuroleptic agents (acepromazine, promazine) in conjunction with narcotic analgesics (meperidine, morphine) reduces the severity of excitation upon recovery.

Methohexital is used on occasion in swine for detusking boars, hoof trimming, foot inspection, and other minor procedures not requiring more than a few minutes. A dose of 5 mg/kg is recommended for these purposes (Emberton 1966).

This ultrashort-acting oxybarbiturate has also been used for performing a ventriculocordectomy in swine held in biomedical research facilities (Mackey et al. 1970). The recommended IV dose of methohexital is 8 mg/kg, which produces surgical anesthesia of approximately 10–15 minutes.

If additional anesthesia is necessary to complete surgery, inhalant anesthetic (ether) has been used. With this combination of anesthetic agents the animals are usually standing within 10 minutes following surgery.

The pig characteristically shakes its head vigorously during recovery from most barbiturates, including methohexital. The animals should recover in a well-padded area and not on concrete floors or other hard surfaces.

In the domestic duck, methohexital administered intravenously has no apparent effect when given in doses of 5–10 mg/kg initially or when followed with additional dosages every 3–4 minutes. It is unclear whether the large fat depots are responsible for this unresponsive effect or if a hyperactive hepatic microsomal enzyme system exists in ducks.

In the rabbit, IV methohexital is given rapidly at 10 mg/kg; it induces light anesthesia within 10 seconds for 2–5 minutes (Wood 1978).

Methohexital (10 mg/kg, IV bolus) has been used in captive and free-ranging muntjac (*Muntiacus reevesi*) for immobilization purposes (Cooper et al. 1986). Although it induces rapid induction of anesthesia, some animals manifest an excitatory behavior during recovery.

Secobarbital Sodium. *Secobarbital Sodium,* USP (Seconal sodium) (sodium 5-allyl-5-[1-methylbutyl]

TABLE 12.5—Median anesthetic dose and average duration of anesthesia in animals

	Methohexital sodium			Thiopental sodium		
Animal	Number of animals	AD50 ± S.E.*	Duration of anesthesia	Number of animals	AD 50 ± S.E.*	Duration of anesthesia
		(mg/kg)	*(min)*		*(mg/kg)*	*(min)*
Dog	15	9.74 ± 0.93	29	15	16.0 ± 0.97	142
Cat	20	5.78 ± 0.54	39	15	10.4 ± 0.92	58

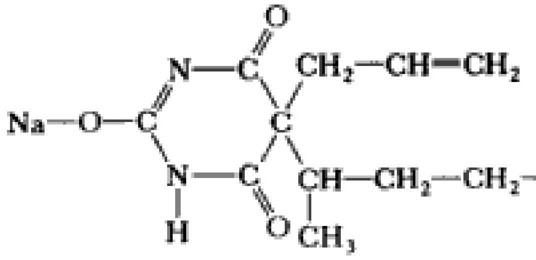
*Standard error.



Secobarbital Sodium

FIG. 12.8

barbiturate), is a short-acting oxybarbiturate and the chemical analog of thiamylal sodium (see Fig. 12.8).

Secobarbital has been used in dogs as an IV anesthetic in combination with mephenesin, a skeletal muscle relaxant. However, this barbiturate appears to be better suited to preanesthetic, basal anesthetic, and sedative uses. Since abdominal relaxation is not satisfactory following mephenesin, its use in combination with barbiturate anesthetics has been virtually discarded. Secobarbital has been used as a sedative prior to EEG recordings because it is purported to have less neurophysiologic effect than many other barbiturates (Strobel and Wollman 1969). Secobarbital and its salts are subject to the 1970 Controlled Substances Act as Schedule II preparations. This drug is discussed in greater detail in the 7th edition of this text.

Hexobarbital Sodium. *Hexobarbital Sodium*, NF (Evipal sodium), is an ultrashort-acting oxybarbiturate infrequently used for clinical purposes. It is subject to the 1970 Controlled Substances Act as a Schedule III drug. A distinct disadvantage of hexobarbital is the uncontrollable excitement and ataxia exhibited during recovery in the dog. In the small laboratory animal, hexobarbital is occasionally used for short surgical procedures. For use in the rabbit, an IV dose of 40 mg/kg will produce anesthesia for 5–10 minutes, with complete recovery in 15 minutes (Murdock 1969). In the adult albino rat, hexobarbital is usually administered intraperitoneally at a dose of 100 mg/kg for induction of anesthesia (Ben et al. 1969). This drug is discussed in greater detail in the 7th edition of this text.

PROPOFOL. *Propofol*, USP ($C_{12}H_{18}O$, Diprivan, Rapinovet, Propoflo), is a chemically unique anesthetic agent used both as an induction agent and as a maintenance anesthetic agent delivered by continuous IV infusion or intermittent bolus (see Fig. 12.9). Propofol has been available for human use since 1989 and was recently labeled for veterinary use in the USA. It is available for both human and veterinary use in Europe. Propofol is insoluble in water so it is available as an emulsion. Initially it was prepared with Cremophor EL, but this was replaced with the currently available emulsion due to the anaphylactoid reactions associated with the Cremophor EL (Branson and Gross 1994; Reves et al. 1994).

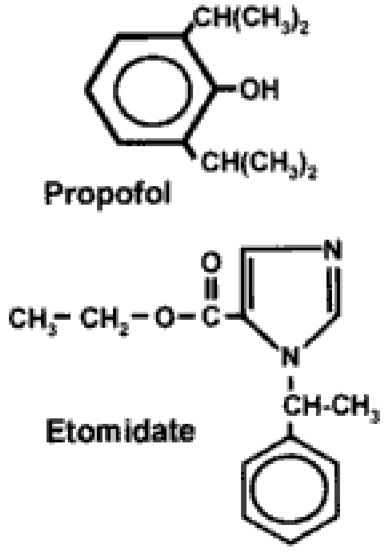


FIG. 12.9

Chemistry. Propofol (2,6-diisopropylphenol) is an alkyphenol that is an oil at room temperature and water insoluble but highly lipid soluble. It is available as an aqueous emulsion containing propofol (10 mg/mL), soybean oil (100 mg/mL), glycerol (2.5 mg/mL), egg lecithin (12 mg/mL), and sodium hydroxide (to adjust pH). It is stable at room temperature and not light sensitive. The formulation available contains no preservatives and will support bacterial growth and endotoxin production (Arduino et al. 1991).

Pharmacokinetics. The pharmacokinetics of propofol in dogs is best described using a two-compartment open model (Zoran et al. 1993). Initially the drug is extensively taken up by the CNS, resulting in rapid inductions. It is then rapidly redistributed from the brain to other tissues and removed from the plasma by metabolism. Propofol's lipophilic nature results in a large apparent volume of distribution (Vd) (17.9 L/kg in mixed-breed dogs); the steady-state volume of distribution (Vd_{ss}) is also large (9.7 mL/kg). The initial distribution half-life ($t_{1/2\alpha}$) is short, as is the plasma disappearance ($t_{1/2\beta}$), due to rapid redistribution of the drug from the brain to other tissues and extensive metabolism. The Vd and Vd_{ss} are smaller in Greyhounds, 11.2 L/kg and 6.3 mL/kg respectively, suggesting sighthounds have slower recoveries, probably due to differences in body composition (Zoran et al. 1993). The pharmacokinetics of propofol in cats has not been determined; however, cats appear to have a similar response to and dose requirement for propofol (Geel 1991; Weaver and Raptopoulos 1991; Morgan and Legge 1989; Brearley et al. 1988).

Metabolism and Excretion. The total body clearance of propofol is rapid and exceeds hepatic blood flow, suggesting extrahepatic metabolism. Indeed, in one study done on human patients undergoing liver transplantation, the amount of propofol metabolite excreted did not decrease when the liver was excluded from the circulation (Veroli et al. 1992). The site of extrahepatic metabolism is not certain, but pulmonary tissue has been shown to contribute to propofol metabolism in cats (Matot et al. 1993) and sheep (Mather et al. 1989). However, there may be species differences in the site and amount of extrahepatic metabolism. Propofol is metabolized to glucuronide and sulfate conjugates, with only trace amounts of other compounds formed. The primary route of metabolite excretion is in the urine, with only small amounts found in the feces (Simons et al. 1991).

Cardiovascular System. Propofol can induce mild arterial hypotension in dogs but the changes are minimal and are due to dose-related vasodilation and decrease in myocardial contractility (Pagel and Warltier 1993). Even in hypovolemic dogs the propofol induced cardiovascular changes were minimal (Ilkiw et al. 1992). In Greyhounds propofol infusion did result in a decrease in the heart rate (Robertson et al. 1992). Propofol can enhance the ability of epinephrine to induce cardiac arrhythmias but does not appear to be inherently arrhythmogenic (Kamibayashi et al. 1991). Propofol can induce oxidative injuries to feline red blood cells if used repeatedly over several days. This can result in anorexia, diarrhea, and malaise (Day et al. 1993).

Respiratory System. The effect of propofol on the respiratory system is similar to that of the thiobarbiturates. Short periods of apnea are commonly seen with propofol administration in dogs. Mild hypercapnia and acidosis are also seen in spontaneously breathing dogs, but neither is severe (Ilkiw et al. 1992; Robertson et al. 1992).

Central Nervous System. Propofol induces CNS depression by enhancing the effects of GABA, an inhibitory neurotransmitter. The site of action is different from that of the benzodiazepines (Reves et al. 1994). Propofol will decrease the intracranial pressure (ICP) in patients with normal or elevated ICP. There is also a decrease in cerebral perfusion pressure associated with propofol administration, and the decrease in perfusion pressure is the major cause of the decrease in ICP (Reves et al. 1994; Wooten 1992). Propofol causes a decrease in intraocular pressure as well. The effect of propofol on seizure activity is not certain. It was initially considered to have no influence on seizure activity, but later studies have shown a dose-related anticonvulsant effect (Heavner et al. 1992). More recently there have been several anecdotal accounts of spontaneous movement and seizure activity during and after propofol anesthesia in humans and dogs. After low doses of propofol, the EEG shows an initial increase in α activity followed by a change to δ and θ frequencies. Increasing plasma propofol levels results in burst suppression (Reves et al. 1994).

Clinical Use. Propofol is used as an induction agent to be followed with inhalation anesthesia and as a maintenance anesthetic. It can be administered by intermittent IV bolus and continuous infusion. It can be diluted for continuous infusion in 5% dextrose, but it should not be diluted to a concentration less than 2 mg/mL. It should only be administered intravenously; pain on injection is regularly observed, especially if small peripheral veins are used. Propofol does cross the placenta and enter the fetal circulation, but it appears to be readily removed from the fetal circulation after birth and produces minimal effects on healthy, newborn, human infants (Dailland et al. 1989). Propofol is used almost exclusively in small animals for economic reasons; however, it has been evaluated in other species.

DOGS. Propofol can be used as a single IV bolus for induction. In unpremedicated dogs the mean dose required ranges from 5.0 to 6.9 mg/kg (Geel 1991; Weaver and Raptopoulos 1991). The induction dose will produce a short period of unconsciousness, usually no more than 2–4 minutes (Morgan and Legge 1989). Premedication with a tranquilizer or other CNS depressants will reduce the dose required by 25% or more. The induction dose required for Greyhounds was not different from that required for mixed-breed dogs; however, the recovery time was longer for Greyhounds. If propofol is to be used as the maintenance anesthetic, it can be delivered as an infusion or as intermittent boluses. A dose of 0.5–2.0 mg/kg is used for the incremental boluses, and they will need to be repeated at regular intervals. The infusion rate will vary somewhat depending on the other drugs used and the amount of surgical stimulation. Since propofol itself is a poor analgesic, an opiate or other analgesic is often used concurrently (Branson and Gross 1994). After premedication with acepromazine and atropine, an infusion rate of 0.4 mg/kg/min produced surgical anesthesia in all patients undergoing various procedures (Hall and Chambers 1987). Lower infusion rates are utilized if more-potent drugs are used concurrently. A propofol infusion rate of 0.25 mg/kg/min produces surgical anesthesia after premedication with xylazine (0.2 mg/kg), fentanyl (0.01 mg/kg), and glycopyrrolate (0.005 mg/kg) (Zoran et al. 1993).

CATS. The reported induction dose of propofol in cats ranges from 5.0 to 8.0 mg/kg (Weaver and Raptopoulos 1991; Morgan and Legge 1989). The reported effect of premedication with acepromazine is somewhat variable, with some reports showing no effect (Geel 1991; Weaver and Raptopoulos 1991; Brearley et al. 1988) and one showing a reduction in propofol requirements (Morgan and Legge 1989). As with dogs, anesthesia can be maintained using intermittent boluses (1.8

mg/kg) (Morgan and Legge 1989) or continuous infusion (0.5 mg/kg/min) (Brearley et al. 1988).

OTHER SPECIES. Propofol (2 mg/kg) was administered to horses following xylazine (0.5 and 1.0 mg/kg) premedication (Mama et al. 1994). The horses given the low dose of xylazine were recumbent for 25 minutes and those receiving 1.0 mg/kg of xylazine were recumbent for 33 minutes. In both regimens the quality of recovery was excellent. Unpremedicated horses were given 2, 4, or 8 mg/kg of propofol intravenously. Administration of 2 mg/kg did not always result in lateral recumbency. When 8 mg/kg was administered, the horses took approximately 48 minutes to stand up and exhibited a decrease in respiratory rate and $PaCO_2$ (Mama et al. 1993). Propofol has also been used in donkeys for induction (2 mg/kg IV) and maintenance of anesthesia after detomidine (0.015 mg/kg IV) premedication. The average maintenance infusion rate was 0.21 mg/kg/min (Hartsfield et al. 1993). In foals propofol (2.0 mg/kg IV) has been used for induction. After induction an infusion at an average rate of 0.33 mg/kg/min was used to maintain anesthesia. The foals were premedicated with xylaxine (0.5 mg/kg IV).

Propofol has been used in rabbits, and the "MAC equivalent" infusion rate has been determined to be approximately 1.2 mg/kg/min (Henderson et al. 1994). Propofol has been used as an induction agent in rabbits premedicated with acepromazine, medetomidine, or medetomidine and midazolam. The IV propofol doses were 10, 4, and 2 mg/kg, respectively (Evans and Eberhart 1992; Ko et al. 1992). In pigs infusions of 9–13 mg/kg/hr did produce anesthesia, but the animals still responded to painful stimuli even at the highest infusion rate. Also, at 13 mg/kg/hr the pigs were apneic (Mascias et al. 1992).

ETOMIDATE. Etomidate (Amidate, Hypnomidate) is a nonbarbiturate IV anesthesia induction agent that does not possess analgesic activity (Owen 1979) (see Fig. 12.9). Induction of anesthesia is rapid (like that of thiopental) (Famewo and Odugbesan 1978). Etomidate administration decreases plasma cortisol levels by slowing the formation of cortisol. This occurs as a result of the inhibition of the enzyme 11-β-hydroxylase. This has been a concern in surgical patients because of the potential for a decreased response to the stress of surgery (Reves et al. 1994). In both humans (Reves et al. 1994) and dogs (Dodam et al. 1990) the plasma cortisol levels are not below normal values.

Chemistry. Etomidate is an imidazole with a chemical formula of *R*-(+)-pentylethyl-1*H*-imidazole-5 carboxylate sulfate. There are two isomers but the (+) isomer is the only one with anesthetic properties. Etomidate is supplied as a 2% solution in 35% propylene glycol. It is not water soluble and is unstable in a neutral solution. The propylene glycol base has been associated with intravascular hemolysis (see Doenicke et al. 1997; Moon 1994; Ko et al. 1993).

Pharmacokinetics. Etomidate appears to fit a three-compartment pharmacokinetic model. The initial primary cause of the return to consciousness after administration of a bolus of etomidate is redistribution from the brain to other body tissues. It has a short redistribution half-life (29 minutes in humans; 21 minutes in cats) and a relatively large steady-state volume of distribution (2.5–4.5 L/kg in humans; 2.5–7 L/kg in cats). The elimination half-life varies from 2.9 to 5.3 hours in humans and is 3 hours in cats (Reves et al. 1994; Haskins 1992). Approximately 75% of etomidate is protein bound in the plasma (Haskins 1992). Because of its rapid redistribution and elimination it is administered both as a single bolus for short anesthesia and as an infusion for longer anesthetic times (Robertson 1992). The drug does cross the placenta but fetal blood levels are appreciably less than maternal blood levels (Esener et al. 1992).

Metabolism and Excretion. Etomidate undergoes hepatic hydrolysis to form a carboxylic acid as a major, inactive metabolite or secondarily undergoes *N*-dealkylation (Reves et al. 1994). The metabolites are excreted via the kidney and bile. Very little is excreted unchanged. Decreased hepatic function prolongs the half-life of etomidate.

Cardiovascular System. The lack of significant cardiovascular effect is etomidate's primary advantage. It has minimal cardiac or peripheral vascular effects in the normal patient (Robertson 1992; Suzer et al. 1998; Tassani et al. 1997). The cardiovascular stability seen in etomidate-anesthetized patients may be due to its lack of response to baroreceptor-mediated cardiovascular control mechanisms (Kissin et al. 1983). There is some evidence that patients with cardiomyopathy may not respond in the same way. An increase in peripheral resistance was seen in animals that had induced left ventricular myopathy (Pagel et al. 1998).

Respiratory System. Respiration is only slightly depressed by etomidate. A dose of 1.5 mg/kg in the dog did not produce significant changes in arterial blood gas values and a dose of 3.0 mg/kg produced only a mild decrease in arterial PO_2 and a mild respiratory acidosis (Nagel et al. 1979).

Central Nervous System. Etomidate's mechanism of action appears to be via an enhancement of the effect of GABA at its receptor site (Tomlin et al. 1998). This effect is limited to the R(+) isomer of etomidate. Etomidate significantly reduces cerebral blood flow and the cerebral metabolic oxygen requirement and produces a decrease in intracranial pressure in patients with elevated intracranial pressure. The effect on the EEG is similar to that of the barbiturates. It has been associated with an increase in EEG activity in epileptogenic foci and is associated with myoclonic movement, but the myoclonic activity is not associated with EEG changes associated with seizures (Reves et al. 1994).

Clinical Use. In animals, the drug has potent hypnotic action and a wider margin of safety than thiopental, methohexital, and propanidid (Janssen et al. 1975; Van Hamme et al. 1978). The therapeutic index of etomidate in the dog is 16. This means the lethal dose is 16 times the clinical dose. The therapeutic index for thiopental is 7 (Robertson 1992).

DOGS. In the dog, IV etomidate produces rapid and safe anesthesia that is hemodynamically safer than thiamylal (Nagel et al. 1979). Dogs given medetomidine (0.015 mg/kg) followed by etomidate given IV at a dose of 0.5 mg/kg and an infusion of etomidate at a rate of 0.05 mg/kg/min exhibited no significant cardiovascular changes related to the etomidate infusion (Ko et al. 1994). Even in hypovolemic dogs, the significant cardiovascular changes associated with etomidate administration are limited to a decrease in heart rate (Pascoe et al. 1992). Loss of consciousness occurs in 15–20 seconds; a small dose (1.5 mg/kg) induces anesthesia for 8 ± 5 minutes, and a large dose (3 mg/kg) produces anesthesia for 21 ± 9 minutes (Nagel et al. 1979).

CATS. Etomidate (0.8 mg/kg) is equipotent to ketamine (5 mg/kg), methohexital (2 mg/kg), and althesin (1.2 mg/kg) administered intravenously in awake cats (Inque and Arndt 1982). Etomidate has been used for anesthetic induction in cats at a dose of 1 mg/kg, after premedication with a tranquilizer (Ilkiw 1994).

OTHER SPECIES. In laboratory mice, etomidate (23.7 ± 1.5 mg/kg) given intraperitoneally permits surgical procedures up to 20 minutes after induction (Gomwalk and Healing 1981). Etomidate can be used as a maintenance anesthetic in pigs at a dose of 0.2 mg/kg with midazolam 0.1 mg/kg (Clutton et al. 1997).

CHLORAL HYDRATE. *Chloral Hydrate,* USP ($CCl_3CH[OH]_2$), was introduced into medicine as a hypnotic in 1869 by Liebrich because it released chloroform in vitro and was thought to do the same in vivo. Subsequent investigation revealed the error of this assumption. It was among the first CNS depressants to be used in veterinary surgery.

Chloral hydrate was first injected intravenously into experimental animals in 1872 by Oré. Three years later Humbert injected 30–70 g intravenously into horses. Chloral hydrate has since been injected intravenously to produce surgical anesthesia in large animals, especially horses.

The drug is classified as a Schedule IV compound under the 1970 Controlled Substances Act.

Chemistry. When acetic aldehyde is chlorinated, trichloroacetaldehyde (CCl_3CHO) is formed. The end product is chloral, a heavy, acrid oil. Chloral combines with one molecule of water to form chloral hydrate. It occurs as colorless, translucent crystals containing not less than 99.5% of $CCl_3CH(OH)_2$. Chloral hydrate volatilizes on exposure to air and has an aromatic, penetrating odor. It has a slightly bitter, caustic taste. One g is soluble in 0.25 mL water and in 1–2 mL of the common fat solvents.

Administration. Chloral hydrate in solution can be injected intravenously and is administered orally in solution or by capsule. Simple-stomached animals generally have little fluid in their stomachs, so the drug is better administered in dilute solution to these species to decrease local irritation to the gastric mucosa. Vomiting is often produced in carnivorous animals from irritation of the gastric mucosa. Presence of food in the stomach reduces irritant effects of the drug upon the mucosa and decreases the likelihood of vomiting.

Chloral hydrate is not a satisfactory anesthetic because it has low pain-relieving power. In addition, so-called anesthetic dosages severely depress the respiratory and vasomotor centers. The anesthetic dosage approaches the LD_{50} and therefore is hazardous.

Chloral hydrate is best employed in the horse for its hypnotic action or for general anesthesia as a basal narcotic with supplementation by thiopental (Crispin 1981). IV injection for hypnotic effect provides the advantage of almost immediate action compared to a delay of 15–30 minutes following oral administration. This drug is discussed in greater detail in the 7th edition of this text.

CHLORAL HYDRATE AND MAGNESIUM SULFATE. A mixture of 12% chloral hydrate and 6% magnesium sulfate in solution for IV injection has been advocated for anesthesia in large animals. This mixture is stable indefinitely. The solution is administered intravenously in horses at a rate not exceeding 30 mL/min to avoid excessive depression of the CNS. Administration is discontinued when the stage of surgical anesthesia appears, as indicated by slowing or absence of nystagmus and other significant reflexes. Anesthesia usually lasts over 30 minutes.

Addition of magnesium sulfate was originally thought to enhance depressant action of the drug mixture through its own depressant effect upon the CNS. It is now known that the magnesium ion exerts little if any direct depressant effect on the CNS (Bowen et al. 1970). The primary effect of magnesium is its neuromuscular blocking action, similar to the curariform agents. From this standpoint, magnesium is beneficial in producing skeletal muscle relaxation, which chloral hydrate does poorly. Inasmuch as magnesium sulfate alone produces only neuromuscular blockade and death due to asphyxia, it is considered inhumane to use it in euthanasia (Bowen et al. 1970).

The combination of chloral hydrate, magnesium sulfate, and pentobarbital sodium (originally marketed under the proprietary names of Chloropent and Equithesin) provides some of the desirable depressant actions of each compound without the individual pronounced toxicities. The original combination proposed by Millenbruck and Wallinga (1946) for anesthesia in horses and cattle consists of chloral hydrate, 30 g; magnesium sulfate, 15 g; and pentobarbital, 6.6 g dissolved in 1000 mL water.

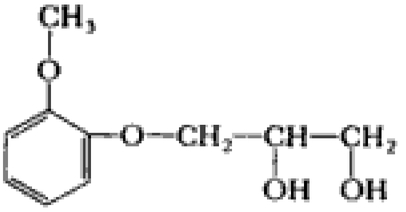
Pentobarbital cannot be added to the solution of chloral hydrate and magnesium sulfate unless it is to be used within about 1 hour. After 2 hours a precipitate forms from exposure of chloral hydrate to the alkalinity of pentobarbital. Commercially, stable solutions are prepared by substituting the relatively insoluble pentobarbituric acid for the soluble sodium salt. Solubility of the acid compound has been increased by use of propylene glycol and ethyl alcohol in the solvent. This drug is discussed in greater detail in the 7th edition of this text.

GUAIFENESIN. *Guaifenesin,* USP (Gecolate, Guaiphenesin Guailaxin), formerly named glyceryl guaiacolate, has been used as a therapeutic agent for over 8 decades. An excellent review of the historical development of medical uses of guaifenesin has been written by Funk (1970). The drug was first used for its analgesic, antipyretic, and expectorant properties. Guaifenesin is chemically similar to mephenesin and meprobamate; it is designated as 3-(0-methoxyphenoxy)-1,2-propanediol (Fig. 12.10).

Guaifenesin has been used as an adjunct to anesthesia in the horse since 1949; in the USA it was first used in 1965. The compound increases the potency of preanesthetic agents and barbiturates. It is a central-acting skeletal muscle relaxant that selectively depresses or blocks nerve impulse transmission at the internuncial neuron level of the spinal cord, brainstem, and subcortical areas of the brain.

Guaifenesin is approved by the FDA as a muscle relaxant for use in the horse but must not be used in animals intended for human consumption. A 5% concentration of the compound is prepared by dissolving the powder (50 g/L) in sterile water.

Stability. Guaifenesin is a white powder with a bitter taste. It is not readily soluble and partially precipitates out of solution at 22°C or lower (Funk 1973). Heating and agitation usually eliminate the precipitate. Only freshly prepared solutions should be used. However, a 10% solution of guaifenesin made in sterile distilled water can apparently be safely stored at room temperature for at least 1 week; the only problem is development of a precipitate (Grandy and McDowell 1980). Guaifenesin appears to possess some bactericidal and bacteriostatic properties.



Guaifenesin

FIG. 12.10

In Australia, a stabilized solution of guaifenesin (Quilate Stabil) for horses has been commercially formulated in a concentration of 15% (Kalhoro and Rex 1984).

Administration and Duration of Action. Although guaifenesin has been administered by all parenteral routes, it is best administered intravenously. Orally, the drug must be administered in high dosages to produce a perceptible effect. Accidental perivascular injection of 5% guaifenesin does not result in severe tissue reaction. However, thrombophlebitis of the jugular vein occurs several days after anesthesia; this effect may be associated with use of guaifenesin (Schatzman 1974).

The primary disadvantage in the use of guaifenesin is the large volume of solution required parenterally to produce relaxation. The effect of the drug is brief (Tavernor and Jones 1970). Duration of action of a single muscle relaxant dose is 15–30 minutes (Pedersoli 1972).

Pharmacologic Considerations. Polysynaptic reflexes are more effectively blocked by guaifenesin than monosynaptic reflexes. A number of literature sources indicate that by itself guaifenesin has sedative, hypnotic, and analgesic effects. There is evidence that sedative and hypnotic effects of the drug are due to the depressant effect upon the reticular formation of the brainstem.

Side effects produced by the drug include a transient decline in systemic arterial pressure when used (200 mg/kg) intravenously in the dog with thiopental and halothane anesthesia (Tavernor and Jones 1970). When used alone in the dog, the effect upon systemic arterial pressure is slight. A tachycardia occurs after the drug is administered, but heart rate returns to normal within 5 minutes after injection.

Guaifenesin (50 mg/mL) in 5% dextrose in combination with xylazine (0.25 mg/mL) and ketamine (1 mg/mL) has been infused intravenously in dogs at the rate of 2.2 mL/kg/hr for over 2 hours without adverse effect (Benson et al. 1985). Continuous infusion of the guaifenesin-xylazine-ketamine mixture does not significantly alter the heart rate, arterial pressure, or systemic vascular resistance. The cardiac index is decreased significantly by the mixture, which may be due to a decrease in stroke volume. An increase in arterial carbon dioxide tension and lowered arterial pH occurs after IV infusion of these three drugs; this coincides concomitantly with hypoventilation that is induced by guaifenesin, xylazine, and ketamine. Benson et al. (1985) did not see ventricular dysrhythmias or ECG signs of myocardial hypoxia or ischemia during the infusion. However, sinus dysrhythmia was observed; it was abolished by IV administration of 0.011 mg/kg glycopyrrolate.

In the horse, IV administration of guaifenesin (160 mg/kg) produces recumbency; minor effects on cardiac and respiratory rates, along with a slight drop in mean systemic arterial pressure and arterial PO_2, occur (Tavernor 1970). In buffalo calves, guaifenesin induces a respiratory acidosis (Singh et al. 1981). Ataxia and muscle relaxation are produced in cattle after an IV dose (50 mg/kg) of guaifenesin; recumbency is induced after an IV dose of 100 mg/kg (Hubbell et al. 1986).

When guaifenesin (80 mg/kg) is administered intravenously in the horse with thiopental (3.5 mg/kg), recumbency and slight decline in mean systemic arterial pressure occur. IV administration of guaifenesin alone (134 ± 34 mg/kg), sufficient to produce lateral recumbency in adult horses, results in a significant ($P < 0.05$) drop in arterial pressure (Hubbell et al. 1980). However, changes in heart rate, respiratory rate, right atrial pressure, pulmonary arterial pressure, and cardiac output are insignificant following administration in horses.

Guaifenesin in therapeutic amounts does not lead to the hazard of paralysis of the muscles (intercostal and diaphragm) of respiration as peripheral-acting skeletal muscle relaxants do. Respiratory activity usually remains normal after a therapeutic dose. In the dog, an IV dose (200 mg/kg) has only a slight effect on arterial PO_2, indicating that alveolar ventilation is unaltered (Tavernor and Jones 1970). Only when doses greater than those recommended are used in therapeutics will respiratory paralysis become a problem. Approximately three to four times the quantity required to produce recumbency of the horse can be administered before death occurs (Funk 1973).

Hemolysis may be induced when concentrations of guaifenesin in excess of 5% are used. However, a few sources in the veterinary literature indicate that hemolysis is insignificant with guaifenesin solutions up to 15%.

Kinetics of disappearance of guaifenesin from blood plasma in the pony have been studied by Davis and Wolff (1970). Of particular interest is the sex difference in rate of disappearance of guaifenesin. Rate of disappearance ($t_{1/2} = 59.6 \pm 4.8$ min) in the female is more rapid than in the male ($t_{1/2} = 84.4 \pm 7.9$ min). This indicates that the drug would need to be administered more frequently to maintain effect in the female, and recovery would be more rapid.

Clinical Use. Guaifenesin has been used in humans, domestic animals, and various species of laboratory animals. The IV dose approved for use of 5% guaifenesin in the horse is at a fixed level of 2.2 mL/kg (110 mg/kg). Most clinical uses in the horse are in line with this dosage (Gertsen and Tillotson 1968; Heath and Gabel 1970; Coffman and Pedersoli 1971; Jackson and Lundvall 1972; Pedersoli 1972).

Guaifenesin (110 mg/kg) given alone and rapidly by the IV route induces recumbency in about 2 minutes for about 6 minutes of light, not quite surgical level restraint (Heath 1977). Premedication with a phenothiazine derivative followed by guaifenesin (110 mg/kg) produces recumbency more easily and rapidly. This provides about 12–14 minutes of light, almost surgical level restraint.

Preanesthetic preparations used intravenously and recommended prior to administration of guaifenesin offer a number of options (Pedersoli 1972): (1) chloral hydrate (4 g/50 kg), (2) promazine (300 mg/454 kg), or (3) acepromazine (0.08 mg/kg).

Usually, guaifenesin (5%) plus an ultrashort-acting barbiturate such as thiopental is administered rapidly by the IV route 10–15 minutes following a preanesthetic level of xylazine. Guaifenesin (60 g) has also been used with pentobarbital (3 g) and 50% dextrose (125 mL) in water up to 1 L (Keeran 1972). A total of 1 L of this preparation is used by rapid IV injection for ovariectomy in adult mares.

Horses may be premedicated with IM acepromazine (0.02–0.05 mg/kg) or an α_2 agonist such as xylazine or detomidine 30–90 minutes before a 10% guaifenesin solution is administered by the IV route through an indwelling catheter (Brouwer 1985). Guaifenesin is given to effect until relaxation of the hindquarters occurs. It is terminated when this effect develops. This is immediately followed by a rapid IV injection of thiopental at a dose of 5.6 mg/kg or 1 g/180 kg. Guaifenesin administered by the above infusion procedure amounts to 48.7 ± 7.7 mg/kg over 3–4 minutes (Brouwer 1985). When about one-half the dose of guaifenesin is administered, the head of the horse drops slightly and light sedation occurs. Continuance of the guaifenesin infusion ultimately leads to relaxation of the hindquarters and swaying. Recumbency occurs 20–30 seconds after the IV bolus of thiopental. According to Brouwer, the limbs and jaw are immediately relaxed, which makes it easy to intubate the trachea for administration of halothane-oxygen. The time of recovery until standing after halothane-oxygen anesthesia and induction with guaifenesin-thiopental is 35 ± 22 minutes (Brouwer 1985).

Guaifenesin as the sole induction agent followed by halothane anesthesia has been used successfully in the horse (Schatzman 1974). When used alone (i.e., not with an ultrashort-acting barbiturate for induction), a higher average respiration rate and a lower, more balanced pulse rate are noted. However, it requires a higher average concentration of halothane to induce and maintain anesthesia.

Administration of xylazine (1.1 mg/kg) intravenously 5 minutes prior to guaifenesin reduces the IV dose necessary to induce lateral recumbency to 88 ± 10 mg/kg in adult horses (Hubbell et al. 1980). Without prior administration of xylazine, the IV dose required to produce recumbency is 134 ± 34 mg/kg.

Guaifenesin, xylazine, and ketamine hydrochloride can be used as a safe method of restraint for casting the horse (Muir et al. 1978). This drug combination minimally depresses cardiopulmonary function even if anesthesia is to be maintained with halothane or enflurane. Moreover, the combination provides safe induction and recovery from anesthesia. Approximately 20 minutes prior to induction of anesthesia with IV guaifenesin (55 mg/kg) in 5% dextrose, xylazine (2.2 mg/kg) is administered intramuscularly. Immediately following induction of anesthesia with guaifenesin, ketamine (1.7 mg/kg) is administered intravenously (Muir et al. 1978). Anesthesia can be maintained with halothane or enflurane. Guaifenesin (50 mg/mL), xylazine (0.5 mg/mL), and ketamine (1 mg/mL) can be used as a continuous infusion for maintenance of anesthesia in horses. It is administered at the rate of 2.2 mL/kg/hr after an induction protocol using xylazine (1.1 mg/kg) IV followed in 5 minutes by ketamine (2.2 mg/kg) IV (Benson and Thurmon 1990). Guaifenesin has been combined with detomidine (40 µg/mL) and ketamine (4 mg/mL) and administered at a continuous infusion rate of 0.8 mL/kg/min (Taylor et al. 1998).

The combination of guaifenesin (50 mg/mL), ketamine (1 mg/mL), and xylazine (0.25 mg/mL) provides effective analgesia in the dog; it is infused intravenously at a rate of 2.2 mL/kg/hr (Benson et al. 1985). In swine a combination of guaifenesin (50 mg/mL), ketamine (1 mg/mL), and xylazine (1 mg/mL) can be used for induction and maintenance of anesthesia. An initial volume of 0.5–1.0 mL/kg is rapidly infused and then 2.2 mL/kg/hr is infused to maintain anesthesia (Thurmon 1986).

Guaifenesin has been used repeatedly at 4- to 8-week intervals in the horse; one animal received the drug 4 times without any adverse effect (Lindley 1976). In a mare with dystocia, guaifenesin (25 g/400 mL) has been used with xylazine (2 mg/kg) and pentobarbital (1 g in the initial 400 mL of solution) intravenously for cesarean section (Cohen 1975). This anesthetic procedure is recommended to save the mare when the fetus is not alive.

It has been shown that a 10% solution of guaifenesin made in sterile distilled water is most suitable for clinical equine anesthesia (Grandy and McDonell 1980). More than 500 horses have been given this concentration without clinical evidence of drug-related problems.

In the mature bull, 5% guaifenesin and 0.2% thiopental in 5% glucose solution is administered (2.2 mL/kg) intravenously for induction of anesthesia (Garner et al. 1975). This is followed with halothane-oxygen for maintenance of anesthesia.

An IV dose of guaifenesin (165 mg/kg) has been used alone in male buffalo calves (*Bubalus bubalis*) (Singh et al. 1981) and in a dose of 90 mg/kg with thiopental (3.6 mg/kg) (Agrawal et al. 1983). A marked arterial hypotension and tachycardia occur in the buffaloes after induction of anesthesia. Also, guaifenesin has been used in IV doses of 27–110 mg/kg in a variety of nondomestic ungulates such as the Przewalski's horse, oryx, eland, and waterbuck (Janssen and Oosterhuis 1984).

Guaifenesin (50 mg/mL) has been combined with ketamine (1 mg/mL) and xylazine (0.1 mg/mL) in 5% glucose for use in cattle and small ruminants. This combination is administered intravenously to produce recumbency (about 0.5 mL/kg); maintenance of anesthesia requires a flow rate of 2.2 mL/kg/hr.

ALTHESIN. Althesin (*Saffan*, CT 1341) is a steroidal preparation containing two pregnanediones for induction of anesthesia (Child et al. 1972a). The anesthetic properties of steroids have been known since the 1940s. A paper published by Hans Selye as long ago as 1941 began the saga of the use of steroids in anesthesiology.

Althesin is in use within Canada and the UK but has not been approved in the USA by the FDA for use in animals. The steroid anesthetic combination has been released for human use in Canada; it may become a useful anesthetic in outpatients undergoing minor surgery (Dunn et al. 1978).

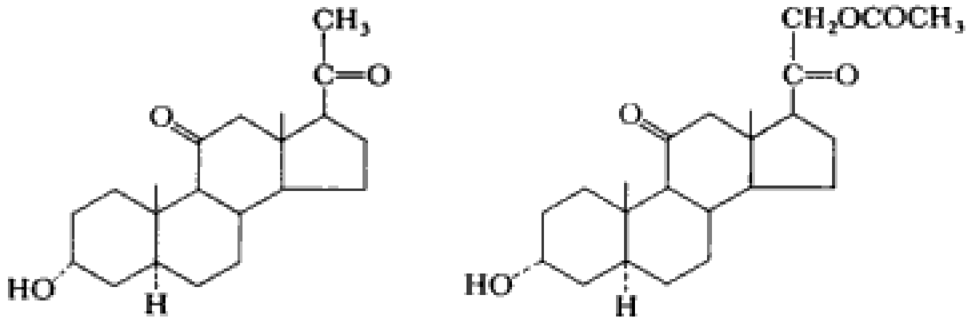
Althesin produces immediate induction of anesthesia of short duration when it is administered intravenously into experimental animals; recovery is rapid and without complications. Anesthetic activity of althesin has been determined in mice, rats, rabbits, cats, dogs, and monkeys (Child et al. 1971).

Chemistry. Althesin contains two pregnanediones, alphaxalone and alphadolone acetate, referred to as steroid I and steroid II respectively (Fig. 12.11) (Child et al. 1972a). A polyoxyethylated castor oil, Cremophor EL, is the vehicle, or carrier substance, for these steroids. IV injection of the vehicle into cats and dogs induces a severe arterial hypotension (Lorenz et al. 1971); this effect is not produced in sheep, rabbits, pigs, or humans.

The anesthetic preparation contains 0.9% weight/volume (*W/V*) steroid I and 0.3% *W/V* steroid II. One mL of althesin contains 12 mg of both steroids, i.e., 9 mg steroid I and 3 mg steroid II. Dosage is expressed as mL formulated solution/kg or mg total steroids/kg.

Pharmacologic Activity. In the cat, 1.2–9 mg/kg althesin administered intravenously produces a transient drop in systemic arterial blood pressure and tachycardia within a few seconds after injection (Child et al. 1972a; Middleton et al. 1982). This is succeeded by a slight rise in blood pressure during recovery from anesthesia. A similar effect upon arterial pressure has been observed by Haskins et al. (1975). On comparing effects of althesin in the cat with ketamine and xylazine (all administered intramuscularly), althesin induces a sustained decrease in arterial systolic pressure of about 23%, while xylazine and ketamine elevate the pressure (Fig. 12.12).

Within 6–9 minutes following injection, Child and coworkers (1972a) reported that animals are able to stand and, after a period of ataxia, a rapid return to normal is observed. An IV dose of 7.2 mg/kg althesin



Steroid I (alphaxalone; 3α-hydroxy-5α-pregnane-11,20, dione)

Steroid II (alphadolone; 21-acetoxy-3α-hydroxy-5α-pregnane-11,20, dione)

FIG. 12.11

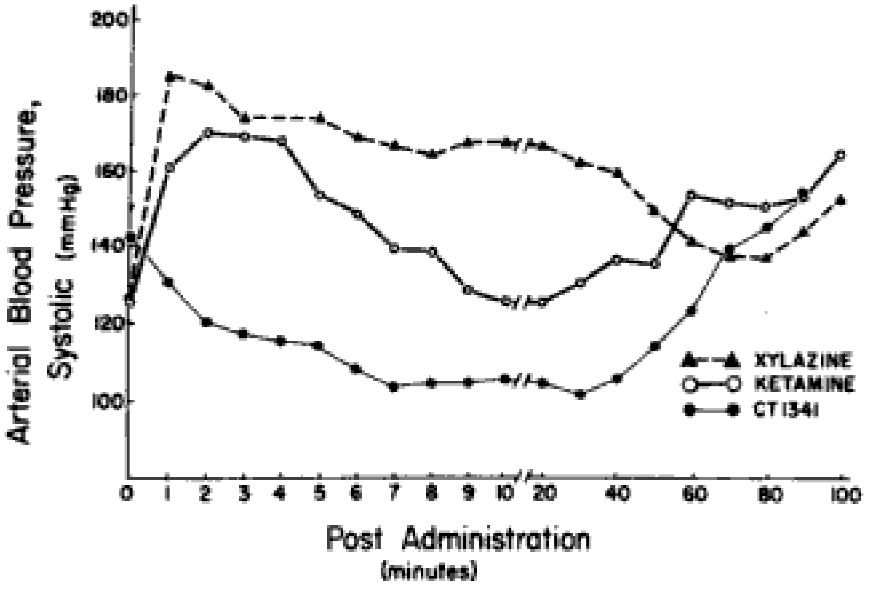


FIG. 12.12—Average systolic blood pressure responses of 4 cats anesthetized with althesin (15 mg/kg), ketamine (33 mg/kg), and xylazine (4.4 mg/kg) (Haskins et al. 1975).

administered 5–10 minutes prior to use of inhalant anesthetics has proved to be a compatible procedure. Cats are satisfactorily maintained for 50 minutes by inhalation agents (Child et al. 1972a). Neuromuscular agents such as succinylcholine, *d*-tubocurarine, or gallamine with althesin are compatible. Preanesthetic agents such as atropine (1 mg/kg) and meperidine (7.5 mg/kg) administered intramuscularly 1 hour before induction with althesin (7.2 mg/kg) are satisfactorily tolerated (Child et al. 1972a).

A dose (0.4 mg/kg) of althesin administered intravenously at a rate of 0.1 mL/kg/sec or 1.2 mg/kg/sec in the cat produces immediate loss of the righting reflex, which lasts for about 1 minute, with complete recovery from ataxia after about 7 minutes (Davis and Pearce 1972). Depth and duration of effect increases as dosage increases, until with 3.6 mg/kg the corneal reflex is absent for 3 minutes. Surgical anesthesia is achieved for 5–10 minutes with a dose of 7.2 mg/kg. Cats tolerate a dose of 19.2 mg/kg with only slight depression of respiration, but 32.4 mg/kg induces apnea, vascular collapse, and death (Davis and Pearce 1972).

Induction of anesthesia with althesin does not potentiate halothane-epinephrine dysrhythmias during halothane maintenance (Dodds and Twissell 1972). An increase in pulmonary vascular resistance in goats occurs following 0.11 mL/kg or 0.22 mL/kg of althesin (Foëx and Prys-Roberts 1972). Heart rate increases 23% with the low dose and only slightly (6%) with the higher dose. Cardiac output increases slightly with the low dose (0.11 mL/kg) and returns to near normal about 1 minute after IV administration of althesin. The higher dose (0.22 mL/kg) decreases cardiac output to almost 20%; it returns to near normal about 4–5 minutes following administration (Foâx and Prys-Roberts 1972). Althesin has less of a negative inotropic action on the myocardium of the cat than thiopental or propanidid (Gordh 1972).

The half-life of alphaxalone in plasma of rats after IV administration of althesin is approximately 7 minutes (Child et al. 1972b). A similar half-life exists in mice and monkeys. Neither alphaxalone nor alphadolone acetate is extensively protein bound in serum of rats, cats, horses, or humans; about 70% of the radiolabeled compounds are excreted in the bile within the first 3 hours after IV administration of althesin. Appreciable amounts of radioactivity appear in both urine (20–30%) and feces (60–70%) for up to 5 days after administration. Gunn rats, a strain deficient in glucuronyl transferase, sleep longer after althesin than normal rats. Apparently, glucuronide synthesis plays a part in metabolism and excretion of these steroids. Preliminary studies with radio-labeled alphaxalone indicate that the major biliary metabolite in the rat is a glucuronide of 2 α-hydroxyalphaxalone (Child et al. 1972b).

Irrespective of the dosage of althesin, Child and coworkers (1972a) observed no injury to the veins and no vomiting in the cat. The IM route of administration (15–18 mg/kg) is useful in kittens where venipuncture is difficult to perform (Hall 1972).

Hormonal effects of althesin have been evaluated in mice, rats, and rabbits (Child et al. 1971). Althesin possesses less than one-sixtieth the activity of betamethasone and is slightly less active than hydrocortisone. In adrenalectomized rats no evidence of mineralocorticoid activity occurs following administration of althesin. Moreover, it does not possess estrogenic or progestational activity in mice. Althesin is capable of antagonizing the uterotropic action of exogenous estradiol; consequently, it possesses weak antiestrogenic activity.

Clinical Use

CATS. Depth and duration of anesthesia with different dosages of althesin have been divided into four easily observable phases (Davis and Pearce 1972): (1) the cat is ataxic, (2) there is loss of the righting reflex and the cat is lying on its side, (3) the pedal withdrawal reflex is absent, and (4) the corneal reflex is absent.

For induction of anesthesia in the cat, a single IV dose of althesin (9 mg/kg or 0.75 mL/kg) has been used clinically for castration and dental surgery (Evan et al. 1972). Duration of anesthesia is 10–12 minutes; surgical procedures requiring more than 5–10 minutes may be extended by injection of additional small amounts of the anesthetic preparation. Even after 48 hours of intermittent administration of althesin, cats awaken within 30–45 minutes of the final injection (Hall 1976).

Althesin can be used to maintain surgical anesthesia for a prolonged period in the cat by repeated supplementary injections of one-half the IV induction dose without significant cumulative anesthetic or respiratory depressant effects (Dodds and Twissell 1973). However, isolated clinical reports have indicated that cessation of respiration occasionally occurs and efforts to revive these animals are unsuccessful.

Althesin may also be administered intramuscularly (9 mg/kg) for clinical procedures such as radiography, dematting, and examination of the mouth (Evan et al. 1972). This dose will produce sedation of the animal in approximately 7 minutes after injection and sedation will last for about 5 minutes. According to Evan and coworkers (1972), 12 mg/kg (1 mL/kg) althesin administered intramuscularly will result in deep sedation or light anesthesia that is sufficient to permit a number of minor surgical procedures such as drainage of an abscess or suturing small superficial wounds. The maximum response produced by this dose level occurs in 7–8 minutes and has a duration of action of about 15 minutes. Light sedation produced by an IV dose of 4 mg/kg has been suggested in premedication prior to induction of full anesthesia with althesin or other anesthetic agents (Evan et al. 1972).

RABBITS. Althesin administered intravenously in the healthy rabbit at 20 mg/kg (one-half rapidly and the remainder slowly to effect) will induce light anesthesia within 1 minute and lasts 6–7 minutes (Wood 1978). Additional althesin (4–6 mg/kg) can be administered intravenously to increase duration of anesthesia. Induction and recovery from althesin is without CNS excitation; full recovery occurs within 30 minutes.

AVIAN SPECIES. Cooper and Frank (1973) concluded that althesin is of value in the chicken when administered by the IV route. Analgesia, muscle relaxation, and speed of recovery were considered to be excellent at an IV dose level up to 14 mg/kg. However, they suggested an IV dose for birds of 10 mg/kg. Althesin appears to be a safe drug even in recently captured birds of prey unaccustomed to restraint. Given by IM and intraperitoneal routes, the drug is of limited value because large volumes are required to induce analgesia (Cooper and Frank 1973).

In the red-tailed hawk (*Buteo jamaicensis*), the dose of althesin should be 5 mg/kg or less intravenously (Cooper and Redig 1975; Cribb and Haigh 1977). Complete sinus arrest, followed in some cases by ectopic beats and then by tachycardia for several minutes, occurs after administration of althesin. Sinus arrest and transient bradycardia followed by tachycardia are seen in mallard ducks (*Anas platyrhynchos*) and Canada geese (*Branta canadensis*). With the high incidence of sinus arrest and tachycardia, it appears that althesin should be used cautiously in red-tailed hawks, mallards, and Canada geese (Cribb and Haigh 1977). Intubation of the trachea in birds is relatively easy because althesin abolishes the swallowing reflex (Harcourt-Brown 1978).

In the budgerigar (*Melopsittacus undulatus*) an IM dose of althesin (36 mg/kg) provides an average of 12 minutes of anesthesia (Curtis et al. 1977). This dose appears to be satisfactory for general use, since repeated dosages can be safely administered if the initial effect is insufficient for induction of anesthesia or if prolongation of anesthesia is necessary. Hypothermia is well recognized following anesthesia of small birds. Maintenance of the bird's normal body temperature during anesthesia and recovery contributes to the safety margin of anesthetics, including that of althesin (Curtis et al. 1977).

A combination of althesin (12–17 mg/kg), ketamine (5 mg/kg), and xylazine (1 mg/kg) injected into the jugular vein has been used to induce anesthesia in ostriches (*Struthio camelus*) (Gandini et al. 1986).

SHEEP. At least 1.65 mg/kg IV althesin is needed to induce anesthesia in sheep (Waterman 1981). The mean arterial pressure decreases 50% at 30 seconds after injection but lasts for only 10 minutes. Premedication with atropine or mepyramine fails to alter this hypotensive action. Injection of the carrier or vehicle Cremophor EL alone has no effect upon mean arterial pressure. Althesin in a mean IV dose of 3 mg/kg is most useful clinically. Infusion of a dilute solution (0.234 mg/kg/min) maintains anesthesia. Sheep recover rapidly from althesin anesthesia.

SWINE. Althesin (1–8 mg/kg) administered intramuscularly into the neck induces slight incoordination with mild sedation to a deep sedative effect and inability to stand in swine weighing 17–93 kg (Cox et al. 1975). Effects of althesin usually occur within 5 minutes of administration, are maximal between 10 and 90 minutes, and are inapparent after 90–180 minutes.

IV administration of althesin (2–3 mg/kg) is followed by loss of consciousness within 10–20 seconds (Cox et al. 1975). Apnea occurs in some animals for 15 seconds after IV administration of the drug. Muscular relaxation is excellent for 4–10 minutes, and endotracheal intubation can be performed during this time without difficulty. Some animals are given azaperone (4 mg/kg) intramuscularly as a preanesthetic 50 minutes prior to althesin.

Preliminary clinical studies indicate that althesin (6–8 mg/kg) induces an excellent sedative effect in swine when injected intramuscularly; in contrast to azaperone, sensory stimuli do not appear to elicit a marked arousal response (Cox et al. 1975). The large volumes of the anesthetic solution required to achieve anesthesia by this route of administration and the expense preclude such use at present. Conversely, according to Cox and coworkers (1975), smaller volumes produce a short period of anesthesia, with excellent muscular relaxation and minimal depression of respiration when the IV route is used. In this respect althesin is superior to combined use of etorphine and acepromazine (Immobilon). Additionally, recovery is rapid, with less struggling compared to use of the short-acting hypnotic (i.e., metomidate hydrochloride). The disadvantage of althesin for induction of anesthesia in the pig is its short duration of action (Cox et al. 1975).

HORSES. Althesin administered intravenously in horses and ponies is associated with CNS excitation for up to 30 seconds after recumbency (Eales 1976). Muscle relaxation is poor. Slight stimulation results in twitching and violent kicking for up to 15 minutes. Althesin does not appear to offer an advantage over presently used anesthetics in equine practice and has several disadvantages (Eales 1976).

BABOONS. Althesin is safe to administer as an IV infusion to baboons premedicated with ketamine (Cookson and Mills 1983). Induction is smooth and recovery is rapid.

REPTILES. Althesin has been used in 13 reptilian species (Lawrence and Jackson 1983). It appears to be an ideal agent for anesthesia in lizards and chelonians.

FISH. Althesin has been used in brown or rainbow trout following immersion in a solution of benzocaine (formerly ethyl aminobenzoate) (50 mg/L). Within 30 seconds fish are sufficiently sedated to permit weighing and subsequent injection of the calculated anesthetic dose (18–36 mg/kg) (Oswald 1978). Althesin is injected by the IP route or a combination of two thirds intraperitoneally and one-third intramuscularly. IM injections greater than 0.2–0.3 mL are not recommended because of reflux of anesthetic solution out of the injection site.

Doses of althesin 18 mg/kg and over produce anesthesia; lower doses only induce sedation. Duration of anesthesia ranges from 1–3 hours at 24 mg/kg to 4–6 hours at 36 mg/kg. Doses of 24 mg/kg and over always induce apnea. Recovery from anesthesia is characterized by a slight phase of excitement and is quickly followed by sedation. In most fish, recovery from althesin is complete within 2 hours (Oswald 1978).

Contraindications and Drug Interactions. Use of althesin in the dog is contraindicated because the nonionic surface active agent (i.e., Cremophor EL or polyoxyethylated castor oil) in the preparation causes release of histamine (Stock 1973), which results in cardiovascular collapse in this species. However, IV Cremophor EL may also liberate mast cell histamine in the cat and induce arterial hypotension, as in dogs (Lorenz et al. 1971). Allergic reactions such as scratching, peripheral edema, hyperemia of the ears, urination, and defecation are regularly seen in cats (Dodman 1980; Middleton et al. 1982). Anaphylactoid reactions may have been responsible for some of the unexpected deaths after administration of althesin (Edmonds 1973; Rheinberger et al. 1979). Moreover, respiratory failure after use of althesin has resulted in death (Ruben 1979).

Apart from barbiturates, any preoperative and postoperative medicant and inhalational agent can be used in conjunction with althesin (Stock 1973). Althesin *must not be used with barbiturates* (Tavernor 1977). Anesthetic adjuvants, including pressor agents, adrenergic blocking agents, and analeptics have been used without adverse effects (Stock 1973). Skeletal muscle–paralyzing drugs have also been used in the cat during althesin analgesia and anesthesia. Only a slight reduction in activity of succinylcholine chloride is noted during prolonged infusion of althesin. No effect on activity of other neuromuscular blocking agents has been observed.

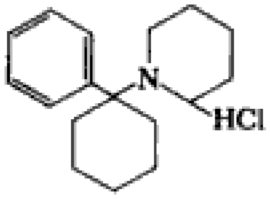
DISSOCIATIVE ANESTHETICS. Three dissociative anesthetic drugs have current interest in veterinary medicine: phencyclidine hydrochloride and its congeners, ketamine hydrochloride, and tiletamine hydrochloride. With a high abuse record in humans, phencyclidine was banned in 1979 for use in the USA. It was moved from Schedule II to Schedule I under the Controlled Substances Act of 1970 but has been reclassified as a Schedule II drug.

A cataleptic-type state referred to as dissociative anesthesia is typical of phencyclidine and its derivatives and is accompanied by marked analgesia in most species (Thurmon et al. 1972). The term dissociative anesthetic originated from use of ketamine in human medicine, which causes the patient to feel dissociated from or unaware of the environment during induction (Price 1975). Ketamine is approved by the FDA for use in the cat and subhuman primates. Tiletamine in combination with zolazepam (Telazol) was approved by the FDA in 1982 for anesthetic use in dogs and cats.

Phencyclidine Hydrochloride. Chemically, phencyclidine hydrochloride (Sernylan, Sernyl, GP-121, CI-395) is 1-(1-phenylcyclohexyl) piperidine hydrochloride (Fig. 12.13). It is a white, glistening solid with a high degree of solubility in water. Phencyclidine is classified as a Schedule II drug under the Controlled Substances Act of 1970.

PHARMACOLOGIC CONSIDERATIONS. Phencyclidine differs greatly from general anesthetics in that absence of responses to nociceptive stimuli is not accompanied with loss of corneal, pupillary, and other reflexes. In most if not all species, phencyclidine in high dosages produces a generalized increase in skeletal muscular tone and catalepsy. It induces stages I and II anesthesia but not stage III anesthesia.

The primary pharmacologic effect of phencyclidine is depression or stimulation of the CNS or a combination of these (Stoliker 1965). According to Stoliker, the quality of the effect produced by phencyclidine is highly species-specific. In mice the principal initial effect is excitation and not depression. However, in the dog and other species, depression is produced by phencyclidine at low dosages; excitation leading to convulsive seizures may occur following large doses (Stoliker 1965).



Phencyclidine Hydrochloride

FIG. 12.13

IM administration of 2 mg/kg phencyclidine in the rhesus monkey results in significant decrease in heart rate about 3 minutes after the injection and lasts 2 hours (Popovic et al. 1972). A corresponding decrease in systolic and diastolic arterial pressures, along with a drop in central venous pressure, occurs. These changes are only significant for the initial 90 minutes. ECG irregularities, along with prominent changes in the QRS amplitude also occur.

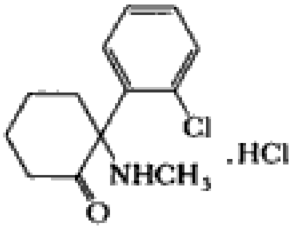
The EEG of phencyclidine-treated monkeys is affected within 3 minutes following injection. Decreases in amplitude of α rhythm and, occasionally, δ waves appear to be reestablished (Popovic et al. 1972).

Three hours later, upon repeated administration of phencyclidine up to one-half the dose (i.e., 1 mg/kg) by the IV route, the drug produces an immediate but temporary decline in arterial pressure, change in the ECG, and catalepsy (Popovic et al. 1972).

A number of authors have referred to the effect of phencyclidine and other central-acting drugs upon behavioral qualities of offspring following use of these agents in pregnant animals. It is suggested by Tonge (1973) that the developing brain of neonates may be particularly susceptible to phencyclidine.

Ketamine Hydrochloride. *Ketamine Hydrochloride*, USP (Ketalar, Ketaset, Vetalar, Ketaject), is a congener of phencyclidine and is chemically designated as 2-(*o*-chlorophenyl)-2-(methylamino)-cyclohexanone hydrochloride (Fig. 12.14).

Ketamine is a unique general anesthetic first introduced into human medicine in 1965; in 1970 it was introduced for anesthesia in the cat. Its lack of cardiorespiratory depression is unequaled by any other general anesthetic currently available (Lanning and Harmel 1975). Ketamine is an extremely versatile agent because it can be administered by the IM or IV



Ketamine Hydrochloride

FIG. 12.14

route without appreciable tissue irritation. Some irritation occurs during IM injection because the pH of an aqueous preparation of ketamine is 3.5.

Adverse effects produced by phencyclidine such as oculogyric activity, tremors, tonic spasticity, and convulsive seizures are ordinarily less pronounced with ketamine. Although ketamine has been approved by the FDA for use only in the cat and subhuman primates, it is being used in most of the other species (Wright 1982). It has not been approved for use in animals intended for human consumption.

Ketamine is classified as a Schedule III drug under the Controlled Substances Act of 1970.

Ketamine is more commonly used in combination with other anesthetic agents. Its use with nitrous oxide and skeletal muscle relaxants provides adequate anesthesia for intra-abdominal and thoracic surgery (Vaughan and Stephen 1974).

Ketamine appears to exert the majority of its CNS actions via its antagonistic effect at *N*-methyl-D-aspartate (NMDA) receptors (Orser et al. 1997). Other evidence suggests it may have effects at other receptors, such as glutamate (Moghaddam et al. 1997; Kress 1997; Sharp 1996; Lees et al. 1994; Goodchild 1993). Ketamine-induced analgesia is mediated at least in part via opiate receptors (Taylor and Kenny 1993; Finck and Ngai 1982).

PHARMACOLOGIC CONSIDERATIONS. In humans, ketamine has been used primarily in children for rapid induction of analgesia. According to Virtue and coworkers (1967), there is presently no more rapid method than IV administration of ketamine.

CNS effects of ketamine, as characterized by the EEG, indicate that depression of the thalamoneocortical system occurs in conjunction with activation of the limbic system. Even though limbic activation including epileptiform EEG patterns develop, there is no evidence that seizure activity spreads to the cerebral cortex (White et al. 1982). Paradoxically, studies have revealed that natural sleep is a more potent stimulant of convulsions than ketamine in the epileptic individual. Consequently, ketamine is not likely to induce convulsions in patients with seizure disorders. Actually, experimental studies indicate that ketamine may have anticonvulsant activity (Reder et al. 1980). However, some of the early and more recent literature refers to ketamine as an "epileptogenic anesthetic" (Oguchi et al. 1982). Until more information is available, ketamine probably should not be used in animals with a history of epileptic seizures. Because of the dual CNS action of ketamine, it is characterized as a dissociative anesthetic.

Ketamine induces anesthesia and amnesia by functional disruption (dissociation) of the CNS through marked CNS stimulation or induction of a cataleptoid state. It induces stages I and II anesthesia but not stage III anesthesia.

Ketamine generally stimulates the cardiovascular system. This effect is thought to be due to central effects that mimic the effect of sympathetic nervous system stimulation. This central stimulation overrides any direct peripheral cardiovascular depressant effects of ketamine (Reves et al. 1994).

Ketamine increases cardiac output, mean aortic pressure, pulmonary arterial pressure, central venous pressure, and heart rate. It has a variable effect upon peripheral vascular resistance. There is evidence that the adrenergic system must be intact for these cardiovascular responses to occur (Christ et al. 1997). Consequently, ketamine probably acts either directly by stimulating the central adrenergic centers or indirectly by inhibiting the neuronal uptake of catecholamines, especially norepinephrine (Adams 1997). These cardiac-stimulating properties, in addition to its antiarrhythmic action, make ketamine a good induction agent for poor-risk and hypovolemic patients (Lanning and Harmel 1975). However, for maintenance, ketamine may be a liability in subjects with severe coronary insufficiency, since it elevates myocardial oxygen consumption. Moreover, dogs made hypotensive by hemorrhaging develop a greater oxygen debt and deteriorate more rapidly with ketamine than with halothane or neuroleptanalgesia. In the isolated perfused rat heart, ketamine alters electrical activity by prolongation of the PR and Q-T intervals (Aronson and Hanno 1978). However, ketamine does not induce major alterations in the ECG pattern of nonhuman primates (Gonder et al. 1980).

Work in the cat has shown that ketamine inhibits efferent cardiac vagal drive by its central action independently of baroreflex function; this central vagolytic effect is believed to be responsible for the positive chronotropic effects of ketamine (Inque and Arndt 1982). Other anesthetics that induce a central vagolytic action leading to tachycardia are althesin and the barbiturates.

An interesting and important pharmacologic effect of ketamine is its effect upon ventilation. Many anesthetics are potent depressants of the ventilatory response to hypoxia, whereas ketamine is not. Ketamine decreases airway resistance in asthmatic patients (human); a bronchodilator such as aminophylline may also be administered before or during ketamine anesthesia without adverse effect (Stirt et al. 1982). In the dog anesthetized with thiopental, an IV combination of ketamine (5 mg/kg) and aminophylline (10, 25, and 50 mg/kg) does not induce cardiac arrhythmias.

When ketamine is used as a monoanesthetic, pharyngeal and laryngeal reflexes remain active (Lanning and Harmel 1975). Preservation of these reflexes, however, leads to increase of laryngospasm, bronchospasm, and coughing secondary to secretions or manipulation in the oropharynx. These complications make ketamine a poor drug for use in endoscopy or oropharyngeal surgery. Additionally, ketamine stimulates salivation, which must be blocked by a noncentrally active antisialagogue (e.g., glycopyrrolate) prior to induction of anesthesia. Also, ketamine increases tracheal-bronchial mucous gland secretions, which is additional justification for using an antisialagogue (White et al. 1982).

As with all general anesthetics, ketamine should be administered with the usual precautions when the stomach is full of ingesta. Nevertheless, presence of a patent airway and lack of respiratory depression make ketamine the general anesthetic of choice when intubation is impossible (Lanning and Harmel 1975). Despite the presence of protective laryngeal and pharyngeal reflexes, tracheal aspiration has been reported after induction of anesthesia by ketamine. Consequently, one should maintain a patent airway or intubate the trachea, as practiced with other anesthetic agents (White et al. 1982).

Clinical case reports in humans have suggested that an interaction occurs between thyroid hormones and ketamine. Human patients on thyroid replacement therapy have developed a severe hypertension and tachycardia following ketamine administration. If such an adverse action occurs, β-adrenergic blocking agents may be of value. Other interactions reported in humans have involved potentiation of respiratory depression and/or paralysis following use of succinylcholine and propanidid (Bovill et al. 1971).

Similar interactions between *d*-tubocurarine have been observed using the cat sciatic nerve–gastrocnemius muscle preparation (Cronnelly 1972; Cronnelly et al. 1973). Potentiation of skeletal muscle twitch of the cat by edrophonium chloride is antagonized by ketamine in IV doses of 1 and 2 mg/kg (Cronnelly 1972). However, ketamine alone produces no significant effect upon muscle twitch (Cronnelly et al. 1973). This is expected, since ketamine produces only a 30% reduction of end plate sensitivity.

Ketamine has been used safely in humans with myopathies and malignant hyperthermia (White et al. 1982). Use of ketamine in animals susceptible to malignant hyperthermia is controversial (Kirmayer et al. 1984).

The combination of IM ketamine (0.55 mg/kg) and acepromazine (11 mg/kg) provides good skeletal muscle relaxation in rhesus monkeys. According to Porter (1982), this combination is useful for surgery or orthopedic work.

Ketamine (2 mg/kg) administered intravenously, increases cerebral blood flow in the dog 80% and cerebral oxygen consumption 16%; EEG changes accompany those of increased cerebral oxygen consumption in that the wave frequency increases after injection of the drug (Dawson et al. 1971). Dawson and associates concluded that ketamine is a cerebral metabolic stimulant and a cerebral vasodilator. They were able to block these pharmacologic effects by prior administration of thiopental.

Ketamine and xylazine have been used in the horse to determine their effects upon intraocular pressure. A decrease in intraocular pressure occurs after an IV dose of 1.1 mg/kg xylazine. Ketamine (2.2 mg/kg) administered intravenously 8 minutes after the xylazine does not induce any further change in the pressure (Trim et al. 1985). The prevalence of nystagmus produced by this combination is considered to be a disadvantage that may complicate ocular surgery. However, maintenance of anesthesia with halothane after ketamine administration is a way to circumvent this complication (Trim et al. 1985).

Ketamine is rapidly distributed into all body tissues, primarily adipose tissue, liver, lung, and brain (Lanning and Harmel 1975). Plasma protein binding of ketamine in the horse averages 50% over the concentration range of 0.3–20 μg/mL (Kaka et al. 1979). Binding of ketamine to plasma and albumin is dependent upon the pH; it is decreased at a pH lower than 7.4 and increased at a higher pH (Dayton et al. 1983).

Biotransformation occurs in the liver by *N*-demethylation and hydroxylation of the cyclohexanone ring, with formation of water-soluble glucuronide derivatives that are eliminated in urine (White et al. 1982). In sheep, metabolites of ketamine have been identified (Waterman and Livingston 1978a). A demethylated metabolite and subsequent oxidation metabolites have been detected in plasma and urine of sheep.

An analytic method for ketamine is capable of detecting 0.1 μg/mL of the compound in blood and urine (Kochhar 1977). This method should be adaptable in detection of ketamine residues in tissue samples.

The apparent biologic half-life of ketamine in humans is 2–3 hours (White et al. 1982). In the horse the distribution (α phase) and elimination (β phase) half-lives of ketamine average 2.9 and 42 minutes respectively following IV injection of 2.2 mg/kg (Kaka et al. 1979).

The elimination half-life of ketamine in the calf is 60.5 minutes (Waterman 1984). Premedication with xylazine does not affect the half-life of ketamine significantly; however, the clearance rate of ketamine is reduced about 50%.

In the cat, a rapid distribution phase ($t_{1/2\alpha}$ = 3 min) is followed by a slower first-order elimination phase (Baggot and Blake 1976). The half-life of ketamine (66.9 ± 24.1 min) is independent of the route of parenteral administration. Absorption from the IM site of administration is rapid; peak plasma concentration is reached in 10 minutes (Baggot and Blake 1976). The elimination half-life of ketamine is prolonged and recovery from ketamine anesthesia is delayed by use of sedative premedicants such as diazepam or secobarbital (Lo and Cumming 1975).

Ketamine anesthesia does not appear to alter endocrine functions in the crab-eating macaque (*Macaca fascicularis*) or rhesus monkeys (Castro et al. 1981; Fuller et al. 1984).

As the result of extensive metabolization of ketamine by the liver, its duration of action is not prolonged in humans with renal impairment (Lanning and Harmel 1975).

Ketamine has a wide therapeutic index. In animals, a ketamine LD_{50}/ED_{50} ratio five times that of pentobarbital has been demonstrated. Repeated administration of ketamine does not lead to development of any significant tolerance or complications. However, ketamine induces the hepatic microsomal enzyme system (Marietta et al. 1977). Although less potent than phenobarbital, ketamine appears to act similarly in induction of hepatic microsomal metabolizing enzymes of rats.

In the cat, body temperature declines by an average of 1.6°C following clinical dosage of ketamine (Beck et al. 1971). Ketamine does not abolish pedal and pinnal reflexes; photic and corneal reflexes persist in the cat as well as laryngeal and pharyngeal reflexes. Skeletal muscle tone is also increased.

When ketamine (3–5 mg/kg) is used intravenously and as the only agent in cats, their eyes remain completely open with a fixed stare and the pupils are dilated. Other clinical signs are licking of the lips and profuse salivation. Increased salivation in cats is consistent with the drug's sympathomimetic action. Slow movements of the head are observed; rigidity or extension of the forelimbs is also seen, and opisthotonus occurs after an IV dose of 8–10 mg/kg. Convulsive seizures have been reported in 5.3% (Beck et al. 1971) and in 20% of the cats that receive clinical dosages of ketamine (Stock 1973). Diazepam has been used to abolish ketamine-induced convulsive seizures in the cat (Reid and Frank 1972). An IV dose of 0.44 mg/kg is used for this purpose. The benzodiazepines (diazepam, lorazepam, midazolam) appear to be most effective in reducing the psychic actions and cardiovascular responses of ketamine in humans upon emergence or recovery (White et al. 1982). In the cat, diazepam used alone induces irritability and aberrant behavior.

According to Beck et al. (1971), IM doses of ketamine less than 22 mg/kg produce basic chemical restraint without total analgesia but are satisfactory for physical examination and minor procedures. IM doses of 22–44 mg/kg produce cataleptoid anesthesia, a comatose state similar to decerebrate rigidity (Beck et al. 1971). This effect is adequate for performing short, simple diagnostic procedures and short surgical procedures; duration of surgical cataleptoid anesthesia ranges from 20 to 40 minutes. Although recovery from ketamine is frequently prolonged and may be accompanied by excitement, the cat is ordinarily able to attain the sitting position after 2 hours (Massey 1973).

The mechanism of ketamine-induced catalepsy has not been extensively investigated and consequently is not clearly understood. With the plethora of literature on catalepsy and other mobility disorders, there is indication that most of these may be due to a deficiency of dopamine function or an imbalance in cholinergic-dopaminergic function. Moreover, other neurotransmitting chemicals cannot be ignored from consideration in catalepsy; e.g., serotonin is also associated with the extrapyramidal system and can induce catalepsy when it is administered intracerebroventricularly in the cat.

When an antiserotonin neuroleptic agent (i.e., methiothepin maleate) is administered in the cat prior to ketamine, it is interesting that the ketamine-induced catalepsy is not observed (Hatch 1973a). Instead of muscle tonus and presence of limb rigidity, which typifies action of ketamine in the cat, muscle flaccidity is observed. Another agent that is an antidopamine neuroleptic (i.e., pimozide) was also employed by Hatch (1973a). The only effect of pimozide on ketamine is that it prevents the sporadic stimulus-induced paw twitch often seen in the cat. The blocking effect of methiothepin upon serotonin suggests that serotonergic mechanisms are involved in ketamine-induced catalepsy, whereas the blocking effect of pimozide suggests that dopamine is involved in the ketamine-induced sporadic movements of muscles and limbs.

The pharmacologic effects of ketamine can be antagonized or shortened almost immediately by administration of a mixture of *l*-amphetamine and yohimbine (Hatch and Ruch 1974). Because yohimbine has been classified as a specific α_2-adrenoceptor blocking agent upon presynaptic receptors (Hedler et al. 1981), antagonism of ketamine may occur from release of central neuronal dopamine and norepinephrine.

ADVERSE EFFECTS. A 2-year-old Giant Poodle with no previous history of respiratory or circulatory complications died of pulmonary edema 2 days after a combination of ketamine (9 mg/kg) and xylazine (1.4 mg/kg) were administered parenterally (Kommonen and Koskinen 1984). Until more clinical experience with this combination of drugs is attained, considerable caution needs to be taken in its use.

CONTRAINDICATIONS AND PRECAUTIONS. Ketamine must not be used in animals intended for human consumption. As the only agent for anesthesia, it is not recommended for use in cesarean section (Dodman 1979). Use of ketamine as the sole agent for abdominal and orthopedic surgery cannot be recommended; its use in major surgical procedures must be supplemented with general anesthesia. Moreover, it is contraindicated in subjects that have arterial aneurysms, uncontrolled arterial hypertension, and right or left heart failure.

Ketamine is contraindicated in animals afflicted with hepatic or renal dysfunction. It is also contraindicated in head injuries, since it elevates the cerebrospinal fluid pressure. Although ketamine is an unlikely agent to trigger generalized convulsions in human patients with seizure disorders (White et al. 1982), it probably should be used cautiously or not at all in animals subject to epileptic seizure.

For procedures involving the pharynx, larynx, or trachea, a probable or relative contraindication to its use is suggested. Also, relative contraindications are suggested in use of ketamine in the presence of increased intraocular pressure or open-globe injury to the eye and in subjects with a thyrotoxic condition (White et al. 1982).

Precautions should be taken to control hemorrhage after surgery because arterial hypertension from use of ketamine occurs; this precaution is especially important following declawing of mature cats, particularly if the paws are not bandaged (Evans et al. 1972).

It has been suggested that it may be prudent to avoid use of ketamine-xylazine in animals that have a reduced cardiopulmonary reserve (Kolata and Rawlings 1982). Use of ketamine alone in patients with respiratory complications is not considered to be contraindicated providing endotracheal intubation, supplemental oxygen, and artificial ventilation are available (Haskins et al. 1985). The combination of ketamine and acepromazine probably should not be used in dogs predisposed to arterial hypotension or respiratory depression (Farver et al. 1986).

Caution is advised in administration of ketamine in animals that have undergone severe hemorrhage. Blood loss of 30% of the total blood volume decreases the anesthetic induction dose of ketamine from 35 to 45% in animals (Weiskopf and Bogetz 1985). In myelographic procedures, ketamine should not be used in seizure-prone animals (Clark et al. 1982).

CLINICAL USE

CAT. Prior to administration of ketamine, atropine or glycopyrrolate should be given to prevent salivation and other autonomic nervous system effects. It is recommended that a bland ophthalmic ointment be used soon after the peak effect of ketamine to prevent drying and irritation of the cornea.

Ketamine is most valuable as an immobilizing agent for examinations, radiographic procedures, and prior to induction of general anesthesia with conventional agents (Glen 1973). The recommended IM dose is from 11 to 33 mg/kg. However, some clinicians use an IM dose as high as 44 mg/kg; 3–5 minutes are required for the animal to become anesthetized (DeYoung et al. 1972). Pain, apparently due to the low pH of the injectable formulation, is elicited during IM injection of ketamine at the dose of 11–44 mg/kg (Evans et al. 1972).

Duration of effects of ketamine following IM injection of 11–44 mg/kg may last 20–45 minutes (DeYoung et al. 1972) and can vary from 15 to 60 minutes (Evans et al. 1972). Recovery may not be complete for 10 hours after administration; however, most animals are able to stand within 2 hours (Evans et al. 1972).

According to Green et al. (1981), an optimum IM dose of ketamine for sedation or analgesia in the cat is 20 mg/kg. Its onset of action is 3 minutes; time to loss of the righting reflex is 10 minutes; time to reach peak effect is 20 minutes; duration of the peak effect is 35 minutes; time to recovery of the righting reflex is 60 minutes; and time to complete recovery is less than 5 hours.

Endotracheal intubation can be achieved during analgesia with ketamine followed by supplementation with an inhalant anesthetic such as methoxyflurane in conjunction with nitrous oxide and oxygen. Nitrous oxide significantly reduces the dose of ketamine required for surgical anesthesia and shortens the recovery period in humans (Wessels et al. 1973). It is the only inhalation agent recommended for use with ketamine in maintenance of anesthesia in humans (White et al. 1982). In the cat, ultrashort-acting barbiturates (thiamylal or thiopental) can also be used in small IV doses (4.4–8.8 mg/kg) to supplement ketamine. Since in the presence of halothane the brain and plasma half-lives of ketamine are longer and recovery from anesthesia is prolonged, caution should be exercised in use of this combination of drugs.

When ketamine is used without intervention of other pharmacologic agents, undesirable side effects occur in many animals (Reid and Frank 1972). By using a combination of oxymorphone (Numorphan) at a dose of 165 µg/kg and triflupromazine (1.1 mg/kg) prior to administration of ketamine, its side effects can be effectively blocked. The dosage of ketamine is reduced by 2.5–10% of the recommended IM dose and is not given until after the peak effect of oxymorphone and triflupromazine has been reached. Both oxymorphone and triflupromazine may be administered by the SC, IM, or IV route. Once the peak effect of these agents is attained, IV ketamine is administered at a dose of 1.1–2.2 mg/kg (Reid and Frank 1972). Ketamine (25 mg/kg) is commonly combined with acepromazine (0.2 mg/kg) and butorphanol (0.4 mg/kg) to provide anesthesia for elective procedures such as ovariectomy (Tranquilli et al. 1988). The addition of acepromazine and butorphanol, an opiate agonist-antagonist, provides improved muscle relaxation and visceral analgesia.

Xylazine has been used prior to ketamine in the cat to prevent muscular hypertonicity (Amend et al. 1972). An IM dose of 0.55–1.1 mg/kg xylazine effectively sedates the cat and renders it relatively insensitive to the subsequent injection of ketamine. Twenty minutes after administration of xylazine, 11–22 mg/kg of ketamine are given intramuscularly. Premedication with xylazine prolongs duration of analgesia, reduces the dose of ketamine required, and shortens recovery time. Disturbances of recovery often noted when ketamine is used alone are eliminated with the combined use of xylazine (Amend et al. 1972).

A combination of ketamine and xylazine is used to induce anesthesia for a number of clinical procedures in the cat (Cullen and Jones 1977). Xylazine (1.1 mg/kg) is administered intramuscularly along with atropine (0.3 mg) by the same route. After 20 minutes, ketamine (22 mg/kg) is administered intramuscularly. Onset of anesthesia occurs on an average of 6 minutes. The palpebral reflex persists during the period of ketamine anesthesia, which lasts about 30 minutes. Supplementation of ketamine anesthesia is achieved with nitrous oxide-oxygen, thiopental, or althesin.

Faulk (1978) reported the satisfactory use of xylazine and ketamine in cats for surgical procedures of less than 1 hour. Xylazine (2.2 mg/kg) is given about 10 minutes prior to ketamine (11 mg/kg); both drugs are administered intramuscularly.

The combination of ketamine and xylazine can induce negative cardiopulmonary changes that are severe (Kolata and Rawlings 1982). It has been suggested that it may be wise to avoid the use of ketamine-xylazine in animals recognized as having or suspected of having reduced cardiopulmonary reserves. In cats given IM injections of xylazine (1 mg/kg) and ketamine (10 mg/kg), the cardiac output is low for 2.5 hours; the prolonged duration of effect may overlap postsurgical complications that could lead to death (Dyson and Allen 1985).

Another clinical approach in reduction of ketamine side effects involves IM injection of acepromazine (0.11 mg/kg) and atropine (0.045–0.067 mg/kg) about 15–20 minutes prior to IM administration of 22 mg/kg ketamine (Rosin 1974). This procedure reduces the dosage of ketamine about 50%.

When ketamine is used in conjunction with meperidine or morphine in the cat, its effects are neither improved nor complicated by these agents (Hatch 1973b). Neither meperidine or morphine appear to have any value as sedative or anticataleptic agents given prior to administration of ketamine.

In fractious cats, ketamine (22 mg/kg) is administered by squirting the drug into the mouth with a syringe when the animal is hissing (Macy and Siwe 1977). This procedure is safe for immobilizing cats. Oral administration induces excessive salivation apparently from the bitter taste or low pH.

Ketamine (22 mg/kg) given intramuscularly interacts with the parenteral administration of chloramphenicol (55 mg/kg) by prolongation of sleep time (Bree et al. 1975). Following administration of dihydrostreptomycin sulfate and procaine penicillin G (Combiotic), relatively no change occurs in duration of sleep time.

NONHUMAN PRIMATES. Ketamine is recommended for restraint and minor surgical procedures in a number of subhuman primates (Beck and Dresner 1972). The usual therapeutic dose recommended for primates is 3–15 mg/kg administered intramuscularly. However, an IM dose as high as 20 mg/kg has been used in patas monkeys (*Erythrocebus patas*) (Britton et al. 1974). This produces safe and adequate sedation for 30 minutes, with minimal respiratory depression. The successful use of ketamine in the infant pigtail monkey (*Macaca nemestrina*) has been reported (Bowden et al. 1974). It is used at an IM dose level of 18 mg/kg prior to an IV injection of thiamylal (15 mg/kg). According to Bowden and coworkers (1974), IM administration of ketamine prior to thiamylal has three advantages: it simplifies the venipuncture procedure for administration of thiamylal, reduces the amount of thiamylal required for induction of anesthesia, and shortens the recovery time.

Parenteral use of 8–10 mg/kg ketamine in the rhesus monkey does not significantly alter length of the menstrual cycle nor lead to significant changes in estrogen or progesterone levels throughout the cycle (Channing et al. 1977). Also, in rhesus and *Macaca fascicularis* monkeys, ketamine anesthesia does not appear to alter endocrine functions (Castro et al. 1981; Fuller et al. 1984).

Heart rate, left ventricular systolic pressure, and respiratory rate decrease significantly in the rhesus monkey following IM injection of 10 mg/kg ketamine (Ochsner 1977). When ketamine (11 mg/kg) and acepromazine (0.55 mg/kg) are administered intramuscularly at the same time in rhesus monkeys, a smooth induction to anesthesia occurs in less than 5 minutes (Connolly and Quimby 1978). The average duration of anesthesia induced by the combination of drugs is slightly less than 1 hour.

Primates immobilized with ketamine have a near normal acid-base balance and are handled more easily than physically restrained animals (Bush et al. 1977). Repeated administration of ketamine on an every-other-day basis up to 60 days in howler monkeys (*Aloutta caraya*) does not lead to habituation (Colillas 1978). The minimum effective IM dose in the howler monkey is 6 mg/kg. After 5 minutes, this induces deep sedation lasting 20 minutes; the animals recover in 18 minutes. In the squirrel monkey (*Saimiri sciureus*), ketamine is satisfactory for chemical restraint at IM doses less than 13 mg/kg (Greenstein 1975). Doses of ketamine of 25 mg/kg and above intramuscularly induce surgical anesthesia in squirrel monkeys; deaths occur only at 350 mg/kg.

In the baboon (*Papio cynocephalus*), a combination of ketamine (11 mg/kg) and xylazine (0.5 mg/kg) administered intramuscularly in a single injection increases sleep time, decreases heart rate, provides good muscle relaxation, prevents voluntary muscle movement, and permits passage of an endotracheal tube (White and Cummings 1979). Ketamine has been used successfully for cesarean section in a 13-year-old gorilla weighing 100 kg (O'Grady et al. 1978). The animal had destroyed three successive infants. To avoid a repeat performance, the period of gestation was estimated by physical examination, radiography, amniocentesis, and ultrasonographic cephalometry. Ketamine (total of 800 mg, or 8 mg/kg) was initially given by injection dart. This was followed by 1 mg atropine intramuscularly. After intubation of the trachea, oxygen was administered along with 50% nitrous oxide. During the operative procedure, which lasted 100 minutes, additional doses of ketamine were given intravenously at 5- to 20-minute intervals. The total dose of ketamine was 2400 mg, or 24 mg/kg. Ketamine has been used as a maintenance anesthetic in the *Gorilla gorilla;* it is administered either by the IV route at 0.5–1 mg/kg or intramuscularly at 1–2 mg/kg (Ludders et al. 1982).

Work in rhesus monkeys indicates that the ketamine-xylazine combination leads to a decrease in alveolar ventilation, with subsequent changes in blood gas tensions, which are probably due to the ketamine content of the combination (Reutlinger et al. 1980). In the event the combination is used, caution must be taken because vital functions are compromised. According to Reutlinger and coworkers, the apparent beneficial effects of the combination that are seen clinically are detrimental physiologically. Presence of the small amount of xylazine in this combination dominates control of the cardiovascular system and abrogates the beneficial effect of ketamine. Conversely, the ketamine component of the combination dominates control mechanisms of the pulmonary system and eliminates to a lesser degree the beneficial effects of xylazine. The end result is that the physiologic effect of the combination has an unfavorable effect upon the cardiopulmonary system (Reutlinger et al. 1980).

DOGS. Ketamine has not been approved by the FDA for use in the dog. However, some practitioners feel that it can be used as safely and effectively in dogs as in cats. Ketamine in combination with xylazine is now commonly used in the dog for general anesthetic purposes. It is also used in combination with diazepam for general anesthesia (Haskins et al. 1986b).

In the discussion of the pharmacologic action of ketamine in the cat it was pointed out that serotonin may function in mediation of catalepsy and that dopamine may mediate ketamine-induced muscle jerking (Hatch 1973a). Studies in the dog indicate that brain mechanisms involved with the various effects of ketamine could be quite different and more complex than those suggested in the cat (Hatch 1974). It appears that dopaminergic and nicotinic chlolinoceptive receptors could be involved in mediation of ketamine anesthesia in the dog. This is particularly suggested because ketamine is antagonized by a subsequent dose of the antidopaminergic neuroleptic pimozide and is partly antagonized by the nicotinic cholinoceptor blocking agent mecamylamine (Hatch 1974). Ketamine-induced muscle jerking and emergent delirium are both enhanced by a subsedative dose of pimozide, by atropine, and by small doses of chlorpromazine. It is known that chlorpromazine possesses both antidopaminergic and anticholinergic actions. All these drug effects suggest that dopaminergic and muscarinic cholinoceptive receptors could have a role in modulating the myoclonic and deliriant effects of ketamine in the dog (Hatch 1974).

Clinically, ketamine (11–22 mg/kg) has been administered intramuscularly 10–15 minutes following atropine (0.045 mg/kg) and acepromazine (0.55 mg/kg) (Kaplan 1972). This has been followed by IV thiamylal (2.5%) administered to effect (usually 0.5–3 mL) about 5 minutes later. Results are less predictable when thiamylal is omitted in the anesthetic procedure. Adverse reactions include a 3.4% convulsion rate, evidence of transient local muscle pain at the site of ketamine injection, and moderate to marked salivation. The dose of atropine must be greater than 0.045 mg/kg to control salivation following use of ketamine. Some dogs with a previous epileptogenic history develop convulsive seizures 2–7 minutes after administration of ketamine and before administration of thiamylal (Kaplan 1972).

Ketamine in doses as low as 5–10 mg/kg given alone and intramuscularly in Beagle dogs induces excitation, apprehension, and, in some animals, tonoclonic convulsive seizures (Green et al. 1981). In IV doses of 10 mg/kg, ketamine administered alone does not produce satisfactory anesthesia for surgical purposes in the dog (Haskins et al. 1985).

Diazepam is used intravenously for alleviation of tonoclonic spasms induced by ketamine; it is used more often than acepromazine in combination with ketamine (Rucker 1976). IV diazepam (0.5 mg/kg) followed by IV ketamine (10 mg/kg) is commonly used to induce general anesthesia in dogs (Haskins et al. 1986a). Muscle hypertonicity related to use of ketamine alone is lessened by diazepam. However, vomiting is increased with this combination.

Acepromazine (0.22 mg/kg) and ketamine (11–17.6 mg/kg) are used in combination (presumably via the IM route) for restraint of aggressive dogs when it is impossible to give an IV anesthetic (Werner 1976). According to Farver et al. (1986), IV acepromazine (0.2 mg/kg) followed 5 minutes later by IV ketamine (10 mg/kg) probably should be avoided in dogs predisposed to arterial hypotension or respiratory depression.

When comparing the IM ketamine (22 mg/kg) and IV acepromazine (1.1 mg/kg) combination with IV xylazine (2.2 mg/kg) alone, it is considered to be superior to xylazine (Gelatt et al. 1976). Xylazine does not provide enough sedation, and during angiography dogs object to the rapid flash of the photo strobe.

Ketamine and xylazine have been used in combination for cesarean section (Navarro and Friedman 1975). Atropine (0.045 mg/kg) is administered intramuscularly and followed by IM xylazine in a dose of 0.55 mg/kg. Ketamine (22 mg/kg) is administered intravenously and given to effect 10–15 minutes following xylazine.

This drug combination is used for minor surgery, dentistry, and restraint during examinations, including radiography (Billiar 1976). Xylazine is given intramuscularly in a dose of 2.2 mg/kg. After approximately 10 minutes, ketamine (11 mg/kg) is administered intramuscularly. In dogs weighing over 22.7 kg, the dose of both drugs is reduced by about 25%. If the ketamine-xylazine anesthesia is insufficient, the animal is intubated so that methoxyflurane can be administered (Billiar 1976). IV xylazine (1 mg/kg) followed 5 minutes later with IV ketamine (10 mg/kg) is a common combination for induction of general anesthesia in the dog (Haskins et al. 1986b).

In the dog (and perhaps other species), the combination of ketamine and xylazine can produce adverse cardiopulmonary changes (Kolata and Rawlings 1982). It has been suggested that it may be prudent to avoid the use of ketamine-xylazine in animals that have or are suspected of having reduced cardiopulmonary reserves. Conversely, the IV infusion of guaifenesin, ketamine, and xylazine appears to provide safe analgesia in dogs, with minimal effect upon cardiopulmonary function (Benson et al. 1985).

A combination of atropine, xylazine, and ketamine in IM doses of 0.044 mg/kg, 1.1 mg/kg, and 22 mg/kg respectively has been used in the dog; xylazine is given 15 minutes postatropine and ketamine is given 5 minutes postxylazine (Clark et al. 1982). Analgesia and restraint with fair to good skeletal muscle relaxation are induced. All reflexes except the ocular are depressed. After administration of xylazine, ECG alterations such as sinus tachycardia, sinus arrest, first-degree heart block, second-degree heart block, and ventricular extrasystole occur. Ten minutes after ketamine is given, the only ECG effect noted is sinus tachycardia. Concurrent with cardiovascular stimulation, respiratory depression occurs, causing less favorable conditions for cardiac metabolism. Alterations in serum chemistry are not significant. One animal had CNS seizures 2 days after anesthesia and after a second anesthetic trial. According to Clark et al. (1982), dogs with cardiopulmonary problems may be at increased anesthetic risk from this drug combination. It is suggested that endotracheal intubation and withholding food prior to anesthesia will reduce the risk of inhalation pneumonia; use of oxygen will prevent myocardial hypoxic conditions that are induced by this drug combination. With these guidelines, clinicians should be able to reach a more informed decision regarding use of the atropine-xylazine-ketamine combination in the dog (Clark et al. 1982).

RABBITS. Ketamine in an IM dose of 44 mg/kg induces anesthesia for 15–30 minutes (Weisbroth and Fudens 1972). In an IM dose of 20 mg/kg, a cataleptoid condition occurs that permits endotracheal intubation (Lindquist 1972). According to Green et al. (1981), ketamine given alone in IM doses ranging from 10 to 60 mg/kg does not provide consistent sedation. Also, analgesia is poor because all rabbits respond to painful stimuli.

A combination of ketamine (75 mg/kg) and promazine hydrochloride (5.6 mg/kg) provides effective anesthesia for 50–60 minutes after a single IM injection (Mulder 1978b). The combined use of ketamine and xylazine in the rabbit has been employed for analgesia in surgical procedures (White and Holmes 1976). Ketamine (35 mg/kg) and xylazine (5 mg/kg) are given as a single IM injection. An optimum level of analgesia and anesthesia is attained after 10–20 minutes.

SHEEP AND SWINE. Although ketamine has not been approved for food-producing animals, it is used in animals such as sheep and swine that are maintained for experimental purposes.

In the use of ketamine in sheep, IM or IV doses of 22–44 mg/kg are adequate for short surgical and diagnostic procedures (Thurmon et al. 1973). Preanesthetic treatment with atropine (0.2 mg/kg) via the IM route is carried out 20–25 minutes before administration of ketamine. Acepromazine (0.55 mg/kg) is given intravenously 15 minutes following administration of atropine, and ketamine is administered 10 minutes later. Additionally, ketamine can be combined with guaifenesin and xylazine and administered intravenously for induction and maintenance of anesthesia (see section on guaifenesin in this chapter).

According to Thurmon et al. (1973), administration of atropine reduces the volume of saliva secreted in sheep. Acepromazine reduces the dosage of ketamine required for a given period of analgesia, increases skeletal muscle relaxation, and prevents reflex movement of the limbs. Conversely, the recovery period in sheep is longer with the use of acepromazine than with use of ketamine alone.

Effects and duration of anesthesia in sheep following IV administration of ketamine have been studied by Waterman and Livingston (1978b). Sheep become ataxic and settle into sternal recumbency following a dose of 2 mg/kg. The animals do not settle into lateral recumbency and appear to remain alert; moreover, there is no evidence of analgesia at this dosage. Respiration is shallow and rapid (30–70 min), and the pulse rate does not change from preinjection values. Animals are able to stand about 8 minutes after injection. At an IV dose of 5 mg/kg, ketamine produces analgesia and anesthesia (Waterman and Livingston 1978b). Pulse rate increases to 100–110/min but drops to the control value of 82 ± 4.5/min within 10 minutes. Respiration is altered to an apneustic pattern that ceases at the time of return of the animal to sternal recumbency. IV doses of ketamine (11.6 and 22 mg/kg) give longer periods of anesthesia (about 15 minutes and 20 minutes respectively) and have a marked effect upon pulse rate. The pulse rate increases to 114 ± 7/min at 1 minute following 11.6 mg/kg ketamine and is 110.7 ± 6.4/min at 5 minutes following injection. At 10 minutes the pulse rate is not significantly different from control levels (94 ± 7/min). An apneustic pattern of respiration persists until sternal recumbency is regained. This is followed by rapid, shallow respiration. Regurgitation of ruminal contents does not occur at any of these dosages of ketamine. Swallowing and palpebral reflexes are present throughout ketamine anesthesia in sheep. Salivation occurs in the unatropinized animal at all dosages of ketamine (Waterman and Livingston 1978b).

Pregnant ewes are successfully anesthetized with IV ketamine (2 mg/kg) followed by a drip infusion (0.2% ketamine in 5% glucose) given at a rate of 4 mL/min during the 1–2 hours of operative procedure (Taylor et al. 1972). Intubation of the trachea is not necessary when the animals are operated upon in the supine position. Moreover, premedication and fasting are not necessary. No vomiting occurred during or following ketamine anesthesia. The rumen did not become distended, and no saliva flowed from the mouth. Consequently, eructation and swallowing must have been present. Nystagmus was sometimes present during ketamine anesthesia. All ewes chewed hay within a few minutes and were standing within 10–15 minutes after removal from the surgical table. Death of one ewe from unknown causes occurred 24 hours after surgery (Taylor et al. 1972).

The experience of Green et al. (1981) with ketamine in sheep is in marked contrast to some of the reports in the literature. They considered that ketamine alone in sheep is not a satisfactory way to induce anesthesia. It is necessary to use xylazine or diazepam to achieve conditions approaching surgical anesthesia. IM xylazine at 0.1 mg/kg 10 minutes before IV ketamine

(4 mg/kg) or IV diazepam (2 mg/kg) about 15 minutes before an initial dose of IV ketamine (4 mg/kg) provides satisfactory anesthesia. This is followed by an IV infusion of ketamine to effect. The combination of xylazine or diazepam with ketamine has an advantage over barbiturate-induced anesthesia; normal eructive and swallowing reflexes are maintained with the ketamine-xylazine or ketamine-diazepam combination. This avoids the problem of ruminal bloating. Nevertheless, Green et al. (1981) found it necessary to intubate the trachea of sheep or goats whenever animals were anesthetized with either of the combinations.

In swine, ketamine has been used intramuscularly at a dose of 20.2 ± 0.92 mg/kg for surgical procedures lasting 10–20 minutes (Thurmon et al. 1972). In longer surgical procedures, ketamine is supplemented with local infiltration of the surgical site with 2% lidocaine, or thiopental is administered intravenously at a dose of 6.6–11 mg/kg.

IM administration of ketamine from 10 to 20 mg/kg alone in pigs induces a distressed or violent reaction in most animals (Green et al. 1981). Ataxia and muscle tremors, including extensor rigidity, panting, salivation, and erythema occur. Consequently, the use of ketamine alone is unsatisfactory in the pig.

A combination of ketamine and acepromazine has been used in miniature swine averaging 23.2 kg (Gray et al. 1978). Acepromazine (0.39 mg/kg) is administered intramuscularly 30 minutes prior to IM ketamine (15 mg/kg). Animals become recumbent 5 minutes following the injection of ketamine and recovery occurs 65–80 minutes later.

Ketamine (11 mg/kg) is used intramuscularly with droperidol-fentanyl (1 mL/13.6 kg) for surgical procedures in swine weighing up to 45 kg (Benson and Thurmon 1979). Droperidol-fentanyl and atropine (0.045 mg/kg) given intramuscularly precede administration of ketamine by 10–15 minutes. Surgical anesthesia is produced in 5–10 minutes and has a duration of 30–45 minutes.

For prolongation of anesthesia, supplemental ketamine is administered intramuscularly (2.2–6.6 mg/kg) or intravenously to effect. Additionally, ketamine can be combined with guaifenesin and xylazine and administered intravenously for induction and maintenance of anesthesia (see section on guaifenesin in this chapter). Pentobarbital (2.2–6.6 mg/kg) is given intramuscularly in larger pigs; it is used in animals with excessive muscle tone or movement and is effective for controlling reactions during recovery (Benson and Thurmon 1979). Ketamine (20 mg/kg) simultaneously with xylazine (2 mg/kg) have been used intramuscularly in swine weighing 20–45 kg (Kyle et al. 1979). The drugs are given following a 24-hour fast period. Sufficient depth of anesthesia is attained within 7–10 minutes.

Xylazine (1 mg/kg) and ketamine (10 mg/kg) have been injected intravenously in rapid succession in the pig (Trim and Gilroy 1985); atropine was not administered. According to Trim and Gilroy, this combination provides excellent immobilization for surgical procedures in healthy pigs weighing about 55 kg. Moreover, they observed that decreases in cardiac output and P_aO_2 were tolerated, with recovery occurring rapidly and uneventfully.

Since more data on the safety and efficacy of the combined use of ketamine and xylazine are needed, caution is advised in their use.

CATTLE. Ketamine (2 mg/kg) for major and minor surgical procedures has been given by rapid IV injection (Fuentes and Tellex 1974). This dose produces rapid onset of dissociative analgesia with no loss of swallowing, palpebral, and anal reflexes. Moreover, there is no appreciable loss of consciousness. Dissociative analgesia is maintained by IV drip infusion of 0.2% ketamine in physiologic saline solution administered at the rate of 10 mL/min. The cattle did not receive preoperative care or premedication. They were fasted 24 hours prior to ketamine anesthesia. The rumen did not become distended, and no regurgitation or salivation occurred. With termination of the ketamine infusion, all animals could stand 30 minutes later. No deaths occurred from ketamine anesthesia (Fuentes and Tellez 1974).

In contrast to the dog, cat, and horse, there are reports in the literature that an additional pharmacologic agent such as xylazine is not required with ketamine to induce skeletal muscle relaxation in cattle (Wright 1982). However, IM administration of ketamine (2–5 mg/kg) is recommended with IM xylazine (0.05–0.1 mg/kg) in calves but not adult cattle; also, IV ketamine (2 mg/kg) may be used after guaifenesin (5%) is administered to effect (Ring and Muir 1982). Guaifenesin is used with ketamine and xylazine in adult cattle (see section under Guaifenesin in this chapter).

GOATS. Ketamine (5–15 mg/kg) given intramuscularly does not produce desirable anesthesia, sedation, or analgesia in the goat (Bowen 1977). According to Bowen, goats resist induction, salivate profusely throughout the 15-minute sedation period, and violently struggle and bleat during the 20-minute recovery period. A similar experience with IM ketamine (20 mg/kg) in the goat has been reported by Green et al. (1981). They considered that ketamine administered alone is unsatisfactory for anesthesia. Use of IM xylazine (0.1 mg/kg) 10 minutes before IV ketamine (4 mg/kg) or IV diazepam (2 mg/kg) about 15 minutes before an initial dose of IV ketamine (4 mg/kg) provides a satisfactory level of anesthesia. This is then followed up by an IV infusion of ketamine to effect. Normal eructive and swallowing reflexes are maintained with the ketamine-xylazine or ketamine-diazepam combination; the problem of ruminal bloating is avoided. Nevertheless, Green et al. (1981) found it necessary to intubate the trachea of goats or sheep whenever animals were anesthetized with either of the combinations. More information is needed on the safety and efficacy of these drug combinations in animals.

A combination of ketamine and xylazine has been used in domestic goats (Kumar et al. 1976); two procedures are described. One consists of administering xylazine (0.22 mg/kg) intramuscularly 8–10 minutes prior to IV injection of ketamine (11 mg/kg). Duration of anesthesia is 40–45 minutes and is prolonged by giving supplemental IM increments of ketamine (6 mg/kg). The second procedure consists of administering a mixture of xylazine (0.22 mg/kg) and ketamine (11 mg/kg), which is injected intramuscularly. For prolongation of anesthesia, a supplemental IM dose of ketamine (9 mg/kg) is administered. In both anesthetic procedures, food is withheld for 24 hours and water for 12. Atropine (0.4 mg/kg) is administered parenterally 20–25 minutes prior to xylazine or ketamine (Kumar et al. 1976). Until the safety and efficacy of the combined use of ketamine and xylazine has been established, caution in their use is recommended.

HORSES. Ketamine, guaifenesin, and xylazine have been used as a method of restraint for casting the horse (Muir et al. 1978). Approximately 20 minutes prior to IV anesthetic induction with guaifenesin (55 mg/kg) in 5% dextrose, xylazine (2.2 mg/kg) is administered intramuscularly. Immediately following induction of anesthesia with guaifenesin, ketamine (1.7 mg/kg) is administered intravenously (Muir et al. 1978). Anesthesia can be maintained with inhalant anesthetics such as halothane or enflurane. Since an interaction between halothane and ketamine has been demonstrated in the rat, the combination of these agents should be used conservatively and with caution until more information is available.

Ketamine (2.2 mg/kg) administered intravenously at the same time or following xylazine (1.1 mg/kg) provides analgesia and light anesthesia in the horse (Muir et al. 1977). Larger IV doses of ketamine (6.6 mg/kg) following sedation with IV xylazine (1.1 mg/kg) are accompanied by muscular tremor and rigidity, oculogyric movements, mydriasis, sweating, arterial hypertension, tachycardia, and elevated body temperature during recovery from anesthesia.

Xylazine (1.1 mg/kg) is administered intravenously about 4 minutes prior to IV ketamine (1.65 mg/kg for ponies, 2.2 mg/kg for horses). This combination provides induction anesthesia for tracheal intubation (Ellis et al. 1977). This anesthesia can be maintained using an infusion of ketamine, guaifenesin, and xylazine (see section on guaifenesin in this chapter).

A combination of ketamine (2 mg/kg) and promazine (1 mg/kg) administered intravenously and simultaneously is used to induce short-term anesthesia in the horse (Fuentes 1978). A state of dissociative anesthesia is induced with a mean duration of 17.1 ± 2 minutes.

A triple drug combination involving diazepam, xylazine, and ketamine provides anesthesia characterized by smooth induction and recovery periods, analgesia with excellent muscle relaxation, and stable cardiopulmonary function (Butera et al. 1978). Diazepam (0.22 mg/kg) is administered intramuscularly. After 20 minutes, xylazine (1.1 mg/kg) is given intravenously, with sedation and moderate ataxia occurring after 2 or 3 minutes. Ketamine (2.2 mg/kg) is given intravenously soon after xylazine has taken effect; about 2 minutes later, the horse becomes recumbent.

It has been reported that ketamine fails to induce analgesia in some horses after using the recommended dose of xylazine (Fisher 1984; Trim et al. 1987). Caution is suggested in the combined use of ketamine and xylazine. More information is needed on the safety and efficacy of this combination in animals.

AVIAN AND EXOTIC SPECIES. Use of ketamine alone in the domestic chicken does not produce satisfactory analgesia. Analgesia is not attained even with large doses of ketamine; this precludes its use as the only agent for inducing anesthesia for surgical procedures (McGrath et al. 1984).

In pigeons, ketamine alone does not produce a state of anesthesia even when used in doses of 400 mg/kg (Bree and Gross 1969). However, anesthesia is achieved by using pentobarbital (20 mg/kg), followed 10 minutes later with 16, 32, or 64 mg/kg ketamine. Both drugs are administered into the pectoral muscles. Induction of anesthesia is smooth and varies from 5 to 30 minutes after administration of ketamine. Mean duration of anesthesia following pentobarbital and ketamine (i.e., after 16, 32, and 64 mg/kg) is 20, 40, and 109 minutes respectively. Anesthesia is maintained for as long as 15 hours in some birds by successive administration of ketamine in doses of 32 mg/kg at 1- to 3-hour intervals. Recovery from anesthesia is uneventful (Bree and Gross 1969). Ketamine doses as low as 0.11–0.13 mg/g in the pigeon result in respiratory failure and death (Boever and Wright 1975).

In the parakeet, ketamine is considered to be a safe anesthetic (Mandelker 1973). A dose of 0.05 mg/g to 0.1 mg/g administered intramuscularly appears adequate. For parakeets and other small birds, ketamine in an IM dose of 2 mg/30 g induces surgical anesthesia in 3–5 minutes and lasts 5–20 minutes (Amand 1977). Anesthesia can be satisfactorily maintained with methoxyflurane (Mandelker 1972). The lethal dose of ketamine for the parakeet is approximately 0.5 mg/g (Mandelker 1973).

Ketamine (0.025 mg/g or 0.05 mg/g) and diazepam (0.0025 mg/g) administered together intramuscularly have been used in parakeets (Green et al. 1981). Onset of anesthesia occurs quickly and without struggling within seconds after the injection. Recovery is rapid after 30–60 minutes of anesthesia.

After induction of anesthesia with ketamine, endotracheal intubation is recommended for giving inhalant agents; most birds weighing more than 100 g can be intubated (Elkins and Herron 1982). Parakeets and canaries are too small for endotracheal intubation. Also, premedication with atropine (0.04–0.1 mg/kg or 0.00004–0.0001 mg/g) has been suggested.

Ketamine has also been used in wildfowl for immobilization purposes (Kittle 1971; Borzio 1973). The

*Administered in conjunction with acepromazine (0.25 mg/kg).

†Used in combination with acepromazine (0.22 mg/kg) and atropine in the same projectile syringe.

§Effects last 1–3 days.

‖Administered subcutaneously.

#Atropine (0.4 mg/kg) is given intramuscularly 15 minutes prior to ketamine; xylazine (0.22 mg/kg) is also given intramuscularly along with ketamine.

**Convulsions occur in some animals.

††Rapid IV injection; intubated for administration of halothane-oxygen anesthesia.

§§Administered intraperitoneally.

##Combined with IM xylazine (0.5 mg/kg).

***Combined with IM or IV xylazine (1–2 mg/kg).

recommended initial IM dose for most wildfowl is 15–20 mg/kg supplemented with increments of 10 mg/kg (Borzio 1973). Immobilization is produced in 1–5 minutes to 6 hours, depending upon the total dose administered.

Baseline values for IM ketamine dosages in various species of birds are as follows (Boever and Wright 1975): (1) birds weighing less than 100 g (canaries, finches, parakeets), 0.1–0.2 mg/g; (2) birds weighing between 250 and 500 g (parrots, pigeons), 0.05–0.1 mg/g; (3) birds weighing between 500 and 3000 g (chickens, owls, hawks), 0.02–0.1 mg/g; (4) birds weighing more than 3000 g (ducks, swans), 0.02–0.05 mg/g. The dose of ketamine is inversely proportional to body weight; larger birds require less ketamine per kilogram of body weight than smaller birds (Boever and Wright 1975).

Large adult birds such as the emu (*Dromiceius novaehollandiae*) that weigh 40 kg are successfully anesthetized with IM ketamine in an initial dose of 25 mg/kg (Grubb 1983). Additional ketamine (about 5–8 mg/kg) is injected intravenously until anesthesia is sufficient for surgical procedures. Ketamine is considered to be much safer in the emu than IV pentobarbital. In the ostrich, ketamine has been used in combination with xylazine and althesin for anesthesia (see section under althesin in this chapter).

For doses of ketamine recommended in exotic species, see Table 12.6.

In Weddell seals (*Leptonychotes weddelli*), deaths occur in some animals when doses of 5 and 6 mg/kg ketamine are administered intramuscularly (Hammond and Elsner 1977). IV or IM atropine (0.02–0.04 mg/kg) and IV diazepam (0.22 mg/kg) given 5–10 minutes prior to IV ketamine (4 mg/kg) provide chemical restraint and anesthesia in California sea lions, northern elephant seals, and harbor seals (Gage 1984).

Ketamine (17–30 mg/kg) and diazepam (0.32–0.58 mg/kg) have been used in combination for anesthetic purposes in river otter (*Lutra canadensis*) (Elmore et al. 1985). The route of administration was not given by Elmore et al. for this combination; the IM route was probably used.

LABORATORY ANIMALS. Anesthesia is achieved in inbred Fisher or Lewis strains of rats with 87 mg/kg ketamine and 13 mg/kg xylazine (Van Pelt 1977). The drugs are mixed together prior to use via the IM route. Anesthesia begins 10–15 minutes after administration and lasts 15–30 minutes; this is followed by a relatively long period of immobility (mean of 3.8 hr) and reduced responsiveness to stimuli.

Ketamine (100 mg/kg) administered intraperitoneally appears to be a suitable anesthetic for use in studies of prolactin secretion in male rats (Meltzer et al. 1978). The anesthetic is known to inhibit uptake of both dopamine and serotonin, two neurotransmitters that have a marked effect on rat prolactin secretion. Anesthetics such as ether, urethane, chloral hydrate, and pentobarbital increase plasma prolactin severalfold (Lawson and Gala 1974).

A combination of ketamine (100 mg/mL), promazine (7.5 mg/mL), and aminopentamide (6.25 μg/mL) provides effective anesthesia in the rat (Mulder and Johnson 1978). The IM dose is 0.75 mL/kg (75 mg/kg ketamine, 5.625 mg/kg promazine, and 46.875 μg/kg aminopentamide). Aminopentamide controls excessive salivation and has other anticholinergic activity. Duration of anesthesia ranges from 41 to 50 minutes, with recovery occurring within 26–34 minutes. About 10% of the animals manifest a transitory CNS excitation that consists of running and jumping during induction of anesthesia (Mulder and Johnson 1978).

IM ketamine (50 mg/kg) plus P diazepam (5 mg/kg) have been used in gerbils (Flecknell et al. 1983). However, anesthesia is not entirely satisfactory because occasional spontaneous limb movements occur.

In laboratory mice, the ketamine-promazine-aminopentamide combination in a dose of 1 mL/kg produces effective anesthesia for 30–50 minutes after a single IM injection (Mulder 1978a). Hyperexcitement is seen in some mice but is not considered to be a serious problem. IM ketamine given alone at 10–400 mg/kg does not induce analgesia even in mice that are heavily sedated; when combined with xylazine, analgesia is insufficient for surgery (Green et al. 1981).

Ketamine (100 mg/kg) given intramuscularly induces anesthesia in the hamster (Hughes et al. 1975). In the golden hamster, the combination of ketamine (50–200 mg/kg) and xylazine (10 mg/kg) administered intraperitoneally is acceptable for general anesthesia (Curl and Peters 1983).

Doses of 22–64 mg/kg and 128–256 mg/kg ketamine given intramuscularly provide tranquilization and anesthesia respectively in guinea pigs. In contrast, Green et al. (1981) reported that IM ketamine (10–150 mg/kg) produced only a mild sedation in guinea pigs. Additionally, the concurrent use of diazepam or xylazine improved skeletal muscle relaxation but did not prevent pain perception.

In the guinea pig (Hartley strain), ketamine (44 mg/kg) and diazepam (0.1 mg/kg) have been administered in combination by the IM route (Gilroy and Varga 1980). Loss of the righting reflex occurs in 1.96 ± 1.06 minutes, and duration of immobilization is 54.6 ± 9.3 minutes. Ketamine (25 mg/kg) and xylazine (5 mg/kg) have been used in combination via the IM route in guinea pigs (Gilroy and Varga 1980). Loss of the righting reflex occurs in 2.88 ± 1.39 minutes, and duration of immobilization is 77.3 ± 14.6 minutes. Although both combinations immobilize guinea pigs rapidly and safely, neither is recommended for general anesthesia because the extent of analgesia induced is uncertain (Gilroy and Varga 1980).

FISH. Ketamine has been used in rainbow trout following immersion in a solution of benzocaine (50 mg/L). Within 30 seconds the fish are sufficiently sedated to permit weighing and subsequent injection of the calculated anesthetic dose (130 or 150 mg/kg) of ketamine (Oswald 1978). Ketamine is injected by the IM route; no more than 0.2–0.3 mL is recommended because of reflux of the anesthetic solution out of the injection site. Ketamine anesthesia lasts only 20 minutes following 130 mg/kg and between 50–80 minutes after 150 mg/kg. Apnea is produced in some fish and requires ventilatory assistance. Recovery is prolonged, taking up to 90 minutes, and is characterized by CNS excitation and ataxia (Oswald 1978).

ANTAGONISM OF KETAMINE ANESTHESIA. In humans, physostigmine antagonizes ketamine; however, it is not antagonized in cats (Hatch and Ruch 1974). This species difference is not surprising because marked variations are known to exist in the concentrations of brain neurotransmitters.

Phencyclidine or its congeners (ketamine, tiletamine) are antagonized by adenosine receptor agonists, N^6-cyclohexyladenosine or 1-phenylisopropyladenosine, in the rat (Browne and Welch 1982). These agonists may possibly be useful in reversal of the CNS effects of ketamine in species other than rats.

In mule deer (*Odocoileus hemionus*), IV yohimbine hydrochloride (0.125 mg/kg) reverses the xyalzine-induced sedation of ketamine-xylazine anesthesia (Jessup et al. 1983).

IV tolazoline (0.5 mg/kg) has been used to reverse the xyalzine-induced sedation of the African elephant immobilized with a combination of IM xylazine (0.2 mg/kg) and IM ketamine (1–1.5 mg/kg) (Allen 1986).

Tiletamine Hydrochloride. *Tiletamine Hydrochloride*, INN (CI-634), like ketamine, is also a congener of phencyclidine. Adverse effects characteristic of phencyclidine are considered to be less pronounced following administration of tiletamine. Chemically, tiletamine is designated as 2-(ethylamino)-2-(2-thienyl) cyclohexanone hydrochloride (Fig. 12.15).

Tiletamine in combination with zolazepam hydrochloride (Telazol, CI-744) was approved by the FDA in 1982 for anesthetic use in dogs and cats. The drug combination is reconstituted in sterile distilled water; this provides both tiletamine and zolazepam with amounts equivalent to 50 mg/mL. Dosage of this preparation is expressed in milligrams of the drug combination.

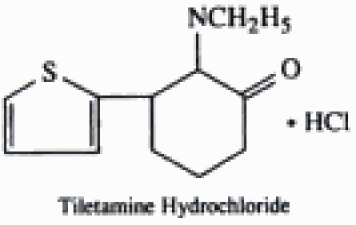

FIG. 12.15

PHARMACOLOGIC ACTIVITY. Most of the pharmacologic characteristics of tiletamine are similar to those of ketamine. The duration of action of tiletamine is about 3 times longer than with ketamine.

Pharmacologic studies have been conducted with tiletamine alone in the mouse, rat, pigeon, guinea pig, rabbit, dog, cat, and monkey (Chen et al. 1967). In mice and rats, CNS excitation is observed; it is not as marked in other species. Tiletamine in large doses induces analgesia and general anesthesia in mice, rats, pigeons, cats, and monkeys. In the guinea pig and rabbit, only CNS depression occurs; anesthesia is not induced in these two species.

Tiletamine alone is more effective in induction of anesthesia in nonhuman primates and in cats than in other species. Increased CNS activity occurs in cats after IM administration of 10 mg/kg tiletamine (Garmer 1969); this includes clonic muscle spasms, particularly in the face and limbs. Administration of 30 mg/kg of tiletamine initiates muscle spasms that progress into a convulsive seizure; it is necessary to administer thiopental for control. A severe metabolic acidosis occurs in cats manifesting clonic muscular spasms. The body temperature drops from 38.5 to 36°C in animals following IM administration of 30 mg/kg tiletamine.

Although it has been reported (Bennett 1969) that tiletamine has moderate to no perceptible effect upon respiratory activity in the cat, Calderwood et al. (1971) are not in agreement with these findings. According to these authors, an irregular respiratory rate, frequently tending toward an inspiratory breath-holding pattern (i.e., apneustic-type pattern), is seen; conversion to a normal pattern may be attained by IV administration of a neuroleptic agent (prozamine or diazepam).

In the cat, a decrease in the heart rate and systemic arterial pressure occurs after an IM injection of tiletamine; it declines to a minimum level within 30 minutes, with a gradual return to normal thereafter. After an IV injection, an elevated arterial pressure and heart rate are observed; also, arrhythmias are frequent following IV administration of tiletamine. In the unanesthetized dog, an IV injection of 2 mg/kg tiletamine results in an increase of arterial pressure and heart rate that lasts about 30 minutes (Chen et al. 1967). A similar dose of tiletamine in dogs anesthetized with pentobarbital also produces arterial hypertension; at higher doses (4–8 mg/kg), hypotension occurs. Doses of 6.6–19.8 mg/kg administered intravenously to dogs awakening from isoflurane anesthesia produced an initial decrease in arterial blood pressure followed by a dose-related increase. Heart rate and cardiac output also increased in a dose-related manner. The highest dose produced a marked decrease in minute ventilation (Hellyer et al. 1989). Premedication with tiletamine does not potentiate the hypertensive response to norepinephrine. Also, no anticholinergic or antihistaminergic effects are seen when tiletamine is compared with the hypotensive effects produced by acetylcholine and histamine respectively. Tiletamine does not produce an emetic effect in cats (Chen and Ensor 1968).

ONSET, DURATION OF ACTION, AND RECOVERY. Tiletamine has an anesthetic induction time comparable to ketamine; it ranges between 1 and 3 minutes in the cat after an IM injection (Chen and Ensor 1968). Duration of the peak effect of tiletamine is about 1 hour, or about 3 times longer than ketamine.

Onset of action after IM injection of tiletamine in the cat begins with the appearance of akinesia; this is followed by motor paralysis of the rear limbs, then the forelimbs (Chen and Ensor 1968). Recovery from the effects of tiletamine varies from 1 to 5 hours in cats given doses of 10–40 mg/kg.

CLINICAL USE. Tiletamine hydrochloride in combination with zolazepam (diazepinone tranquilizer) is available in a 1:1 ratio. Undesirable side effects are seen when the components of the combination are administered alone or separately; combining these agents yields a compatible preparation with desirable anesthetic, analgesic, and ataractic properties (Booker et al. 1982).

DOGS. Tiletamine and zolazepam (6–13 mg/kg) given intramuscularly produce satisfactory anesthesia for surgical procedures lasting 30–60 minutes (Ward et al. 1974). An initial IM dose of the combined preparation approved by the FDA in healthy dogs is 6.6–9.9 mg/kg for diagnostic procedures; for surgery of short duration (30 minutes) requiring mild to moderate analgesia, such as repair of wounds and castrations, an IM dose of 9.9–13.2 mg/kg is approved. Additional doses of tiletamine-zolazepam, when required, should be less than the initial dose; the total IM dose should not exceed 26.4 mg/kg. The maximum safe IM dose is 29.9 mg/kg in dogs. IV administration of 9.9 mg/kg resulted in more rapid inductions and a similar duration (Tracy et al. 1988). Smaller doses administered intravenously (2 mg/kg and 4 mg/kg) produced slightly shorter anesthetic times (Donaldson et al. 1989). The quality of recovery is somewhat poorer in dogs than in cats. This is probably due to the relatively more rapid metabolism of zolazepam in dogs than in cats (Tracy et al. 1988). Interaction of tiletamine-zolazepam with chloramphenicol in the dog has no apparent effect upon duration of surgical anesthesia or time of recovery (Bree et al. 1976a). This is in contrast to the cat, in which duration of surgical anesthesia and time of recovery are increased by chloramphenicol (Bree et al. 1976b). Telazol (8.8 mg/kg) can be combined with xylazine (1.1 mg/kg) and butorphanol (0.22 mg/kg), all administered intramuscularly, to provide approximately 70 minutes of good muscle relaxation and anesthesia. Anticholinergics will effectively treat bradycardia, and minimal respiratory depression occurred (Benson et al. 1989).

CATS. IM doses of 6–13 mg/kg tiletamine and zolazepam provide satisfactory anesthesia for surgical interventions of 30–60 minutes (Ward et al. 1974). An initial dose of 8.8–11.9 mg/kg is approved by the FDA in healthy cats for dentistry, incision of abscesses, foreign-body removal, and other similar procedures; for surgery requiring mild to moderate analgesia, such as repair of lacerations, castration, and other procedures of short duration (30 minutes), an IM dose of 10.6–12.5 mg/kg is approved. Also, the FDA has approved an initial dose of 14.3–15.8 mg/kg tiletamine-zolazepam for ovariohysterectomy and onychectomy. Supplemental IM doses should be administered in increments that are less than the initial dose; the total dose (initial plus supplemental doses) should not exceed 71.9 mg/kg (the maximum safe dose). In cats, IV doses of 12.8 mg/kg produced anesthesia of approximately 30 minutes duration (Tracy et al. 1988).

Chloramphenicol therapy increases the mean duration of surgical anesthesia by approximately 30 minutes; it also increases the time to return of the righting reflex by about 2–2.5 hours and time to return to normal by about 3 hours (Bree et al. 1976b). This interaction with chloramphenicol can be avoided by not anesthetizing animals with tiletamine-zolazepam. Unlike the interaction with chloramphenicol, cats wearing flea collars do not have an apparent interaction after tiletamine-zolazepam anesthesia (Bree et al. 1977).

NONHUMAN PRIMATES. Dissociative anesthesia provided by tiletamine-zolazepam is suitable for surgical procedures and restraint, particularly for physiologic studies in the rhesus monkey (Booker et al. 1982). An IM dose of 3 mg/kg of the anesthetic combination produces anesthesia for minor surgical procedures.

Tiletamine-zolazepam has been used in 51 primate species (Eads 1976). Adverse reactions totaling 71 (2.9%) out of 2342 anesthetic procedures have been observed; this includes salivation (2.14%), respiratory depression (0.3%), prolonged recovery (0.26%), and emesis (0.21%). Also, 3 deaths resulted after administration of the anesthetic combination.

LABORATORY RODENTS. Tiletamine-zolazepam (20–30 mg/kg) given intramuscularly in the rat provides satisfactory anesthesia for surgical procedures of 30–60 minutes (Ward et al. 1974). The combination is not effective for mice or hamsters (Silverman et al. 1983).

GUINEA PIGS AND RABBITS. In the guinea pig and rabbit, lack of skeletal muscle relaxation and response to external stimuli make tiletamine-zolazepam unsatisfactory for surgical anesthesia (Ward et al. 1974).

OTHER SPECIES. Tiletamine-zolazepam has been administered intravenously in calves (4 mg/kg) with minimal cardiovascular and respiratory changes (Lin et al. 1989). This dose produced light anesthesia for approximately 50 minutes. The addition of xylazine (0.1 mg/kg) produced transient hypertension and a moderate decrease in cardiac output. The duration of anesthesia was also increased (Lin et al. 1991). Pigs receiving 6 mg/kg of tiletamine-zolazepam with 1.1 or 2.2 mg/kg of xylazine (all given IM) rapidly became recumbent and remained unresponsive to stimuli for an average of 47 (low dose) or 68 (high dose) minutes (Thurmon et al. 1988). Tiletamine-zolazepam has been administered to horses in combination with xylazine or detomidine. The dose of tiletamine-zolazepam ranged from 1.1 to 3.0 mg/kg and produced anesthesia of up to an hour duration with the high dose (Lin et al. 1992; Hubbell et al. 1989).

EXOTIC SPECIES. Tiletamine-zolazepam has been used in the chinchilla (Schulz and Fowler 1974). Surgical anesthesia is produced by IM dose levels of 22–110 mg/kg; however, some deaths occurred at doses of 66 mg/kg and above.

Clinical trials indicate that tiletamine-zolazepam has a wide margin of safety for restraint and immobilization of the red kangaroo (*Macropus rufus*); adequate anesthesia and muscle relaxation are obtained with IM doses of from 2 to 6.9 mg/kg (Boever et al. 1977). In lions and leopards, tiletamine-zolazepam has been used for induction of anesthesia; dosage is expressed in mg/kg$^{0.75}$ and related to duration of anesthesia by use of regression equations (King et al. 1977). Male lions and leopards are more susceptible to the CNS depressant effects of tiletamine-zolazepam than females; males are anesthetized 15 minutes longer for a given dosage.

Tiletamine-zolazepam (5 mg/kg) given intramuscularly has been used in polar bears (Haigh et al. 1984). It is considered to be an ideal immobilizing preparation for ear-tagging procedures.

In reptilian species, tiletamine-zolazepam provides suitable anesthesia for surgical procedures only in iguanas; IM doses of 33 and 44 mg/kg produce surgical anesthesia lasting about 16 hours (Boever and Caputo 1982). Use of IM tiletamine-zolazepam (22, 33, or 44 mg/kg) in snakes produces a deep CNS depression; it may be necessary to supplement with an inhalant agent to abolish reflex activity suitable for anesthesia. In turtles, tiletamine-zolazepam is not acceptable as a surgical anesthetic agent (Boever and Caputo 1982).

PRECAUTIONS AND CONTRAINDICATIONS. Tiletamine-zolazepam must not be used in pregnant animals or in those that have pancreatic, renal, cardiac, or pulmonary dysfunctions. The drug combination should be reduced in geriatric animals. The unused reconstituted solution of tiletamine-zolazepam must be discarded after 48 hours.

MISCELLANEOUS AGENTS

Chloralose. The family of compounds called chloraloses (α-chloralose, monochloral *d*-glucose) are prepared by condensing anhydrous glucose with chloraldehyde (chloral) in the presence of sulfuric acid. A mixture, 3 dichloralglucoses and 2 monoglucochloraloses (i.e., α-chloralose and β-chloralose), is formed. In the experimental laboratory α-chloralose is used more frequently than any of the other chloralose preparations. It is usually administered intravenously in 1% concentration. However, concentrations of 10% have been prepared by using an inert dispersing agent such as polyethylene glycol (Bass and Buckley 1966).

Chloralose is difficult to dissolve in an aqueous medium without simultaneous heating. Because of deterioration, chloralose solutions should not be boiled. After solution is accomplished, the preparation is allowed to cool to the approximate body temperature of the animal before IV injection.

Chloralose is metabolized to chloraldehyde or chloral, which is mainly transformed into trichloroethanol. Hypnosis and anesthesia produced by chloral hydrate and chloralose are quite similar because of formation of trichloroethanol.

Chloralose possesses the unique characteristic of altering the mental component of CNS activity while increasing reflex activity. Spinal reflex activity may increase to the degree that convulsions similar to those of strychnine develop in the dog and cat (Lees 1972). Functional disruption (dissociation) of the CNS through marked CNS stimulation or induction of a cataleptoid state typifies the action of chloralose (Winters 1976). It induces stage I and stage II anesthesia but not stage III.

The oral LD_{50} of chloralose for rats, cats, and dogs is 400–600 mg/kg (Balis and Monroe 1964). For the IV or IP routes, it is 120–150 mg/kg. In dogs and cats, 40–100 mg/kg IV injection may produce violent tonic convulsions resembling strychnine poisoning.

As an anesthetic agent, chloralose is restricted to laboratory animals in which recovery from anesthesia is not necessary. It is used primarily in physiologic experimentation because it purportedly does not interfere with respiratory and cardiac reflexes, e.g., baroceptor and chemoceptor activities.

Use of IV chloralose (100 mg/kg) in the dog has followed a sedative IV dose (1 mg/kg) of xylazine for myocardial function studies (Caffrey et al. 1985). Combination of xylazine with chloralose should lessen gross movements such as limb paddling that often occur with use of chloralose alone.

In the dog and cat, the IV dose of chloralose is between 40 and 100 mg/kg; anesthesia lasts 6–10 hours (Lees 1972). It is usually administered with ether to reduce spinal reflex activity and "convulsive-like" actions associated with use of chloralose. The cardiovascular responses following IV administration of chloralose (100 mg/kg) have been studied extensively in the dog (Cox 1972). With the exception of brief effects immediately after injection, which last about 15 minutes, there are no changes in systemic hemodynamics. In the cat, chloralose (75 mg/kg) is commonly used intravenously for anesthesia in the research laboratory.

Chloralose has been used in sheep at a dose of 48–55 mg/kg. Onset of action is delayed following administration and does not attain its full effect for at least 20 minutes. In swine, following premedication with a small dose of morphine, the IV dose of chloralose required to induce an effect is 55–86 mg/kg. Paddling movements of the limbs are observed in the pig similar to those seen in sheep.

In the UK, chloralose is employed for killing rats and is available to the general public (Lees 1972). Cases of suspected chloralose poisoning have been reported in the dog and cat (Copestake 1967). The drug apparently is also being illegally used in baits against crows, gulls, and foxes (Conder 1973). However, other birds (golden eagle, buzzard, hen harrier), whether intended or not, also receive the bait and have died from its use.

In the USA, chloralose has been used to capture wild turkeys and mourning doves (Cline and Greenwood 1972) and has been used with diazepam for capture of Canada geese.

Urethane. *Urethane,* NF ($NH_2COOC_2H_5$), is also known as ethyl carbamate. It is chemically related to urea and is readily soluble in water and alcohol. Urethane is used only occasionally as an anesthetic in laboratory animals and then only in nonsurvival or acute experiments. The drug can be administered intravenously (1 g/kg) or intraperitoneally (1–2 g/kg). In small laboratory animals such as the rat, urethane (1.25 g/kg) is administered intraperitoneally.

Urethane is not used clinically because there are safer anesthetics available. It produces anesthesia that lasts many hours. It is metabolized slowly into carbamic acid and ethyl alcohol. Liver injury is produced by urethane. The rate of elimination is so slow that pulmonary edema usually occurs before the animal fully recovers from anesthesia. In addition, urethane has a carcinogenic effect in several species.

Propanidid. Propanidid (Epontol, Fabantol, Fabontal) is a nonbarbiturate IV anesthetic used for inducing anesthesia in humans. It induces CNS excitatory side effects with either rigidity or uncontrolled movement (Steen and Michenfelder 1979). When given to epileptic patients, propanidid (like ketamine) triggers seizure activity.

Propanidid (17.7 mg/kg) given intravenously induces hypnosis in rats; an IV dose of 50 mg/kg is necessary to induce sleep for 2–5 minutes (Janssen et al. 1975). After administration of 50 mg/kg, recovery requires 9 minutes.

Metomidate. *Metomidate,* INN (Hypnodil), is a nonbarbiturate drug recommended for anesthesia in birds of prey (Cooper 1974a; Cadle and Martin 1976). It is administered intramuscularly into the leg using a 1 mL tuberculin syringe and a 25- or 23-gauge needle. Doses of metomidate range between 8.8 and 16 mg/kg for various species. Some deaths have occurred following repeated use at doses of 10 mg/kg and above. Duration of anesthesia ranges from 70 to 165 minutes. In birds, other drugs generally are not administered with metomidate; occasionally, maintenance of anesthesia may require supplemental use of an inhalant anesthetic. However, metomidate has been used with azaperone in swine.

Metomidate (50 mg/kg) plus fentanyl (0.05 mg/kg) given subcutaneously consistently produces surgical anesthesia in two species of gerbils (Flecknell et al. 1983). In the dog, IV metomidate (4 mg/kg) has been used in combination with xylazine and a phenothiazine tranquilizing agent (Holenweger et al. 1984).

Metomidate is not available for use in the USA. It is used primarily in the UK and other countries.

OPIOID AGONISTS AND ANTAGONISTS

KEITH R. BRANSON AND MARJORIE E. GROSS

Opioid Source and Composition
Opioid Receptors
Endogenous Opioids
Opioid Pharmacodynamics
  Full Agonists
  Full Antagonists
  Partial Agonists
  Agonist-Antagonists
Opioid Agonists
  Morphine Sulfate
  Codeine Phosphate
  Hydromorphone Hydrochloride
  Oxymorphone Hydrochloride
  Meperidine Hydrochloride
  Methadone Hydrochloride
  Fentanyl Citrate
  Sufentanil Citrate
  Alfentanil Hydrochloride
  Carfentanil Citrate
  Remifentanil Citrate
  Etorphine Hydrochloride
  Propoxyphene Hydrochloride
Opioid Antagonists
  Naloxone Hydrochloride
  Diprenorphine Hydrochloride
  Levallorphan Tartrate
  Naltrexone
  Nalmefene
Opioid Partial Agonists
  Buprenorphine Hydrochloride
  Tramadol Hydrochloride
Opioid Agonist-Antagonists
  Nalbuphine Hydrochloride
  Pentazocine Lactate
  Butorphanol Tartrate
  Nalorphine Hydrochloride
Opioids and Spinal Analgesia
Opioids and Peripheral Analgesia

The analgesic drugs play an important role in the clinical practice of veterinary medicine. Lloyd E. Davis (1983) succinctly described the correct role of analgesic therapy:

> One of the psychological curiosities of therapeutic decision making is the withholding of analgesic drugs, because the clinician is not absolutely certain that the animal is experiencing pain. Yet the same individual will administer antibiotics without documenting the presence of a bacterial infection. Pain and suffering constitute the only situation in which I believe that, if in doubt, one should go ahead and treat.

Pain management also is of increasing importance in laboratory animal medicine. Guidelines were issued in January 1975 by the US Department of Agriculture, which has the responsibility for enforcing the US Animal Welfare Act, to ensure appropriate use of pain-relieving drugs by biomedical research laboratories. Regulations of the act place considerable responsibility upon the attending doctor of veterinary medicine to ensure appropriate use of analgesic agents in experimental animals.

Although other classes of drugs produce analgesia, the primary type of drug used for analgesia has been, and will probably continue to be, the opioids. Since the 1960s, analgesic agents such as fentanyl, oxymorphone, etorphine, and others have been introduced for use in animals. These agents are important in alleviation of pain and are valuable in facilitating restraint and handling of animals.

In 1978, carfentanil citrate, a fentanyl analog, was introduced for use in human medicine; 2 years later another analog, named alfentanil hydrochloride, appeared on the scene. Carfentanil has been used in several species of wildlife for immobilization purposes. Another analog of fentanyl, sufentanil citrate, was introduced for human use in 1984. Its duration of action is shorter and about 10 times more potent than fentanyl in the dog (Reddy et al. 1980). The most recent fentanyl analog, remifentanil, became available for human use in 1996.

Numerous other synthetic opioids have also been developed in an attempt to minimize the undesirable effects of these drugs. These chemically diverse compounds take advantage of selective activity at opioid receptors.

The increasing practice of combining an analgesic agent with neuroleptic drugs (droperidol and the phenothiazine tranquilizers) or α_2 agonists has expanded the number of preparations the veterinarian can use for neuroleptanalgesic purposes.

OPIOID SOURCE AND COMPOSITION. Opium has been used in medicine since the dawn of history. It was recommended for relief of pain in the *Papyros Ebers*, written about 1500 BC. Greek, Arabian, and Roman physicians were well versed in the uses of opium. Arabian traders introduced it into the Orient. Opium has been widely used by physicians throughout the world from times of earliest record, through the Dark Ages in Europe, the Renaissance, and to the present day. During the eighteenth century, Portuguese merchant shippers promoted its use in China solely for economic exploitation. Armed conflict resulting from this and other exploitations led to international regulation of opium commerce by the former League of Nations and now by the United Nations.

Within the USA the Drug Enforcement Agency of the Justice Department maintains a large workforce to regulate and control importation, processing, sale, and dispensing of all opium and its alkaloids, since it is capable of producing addiction in humans. On May 1, 1971, the Controlled Substances Act of 1970 was implemented; it superseded the Harrison Narcotic Act of 1914. With the exception of heroin and some other opiate derivatives, morphine and all derivatives are classified as Schedule II drugs. Heroin is classified as a Schedule I drug because it has no accepted medical use in the USA.

The addictive property of morphine is of little direct importance in animal medicine because generally animals are not given the opportunity to develop drug dependence. However, development of addiction in humans has led to restrictions that have caused many veterinarians to forgo use of morphine and morphine substitutes in their practice. This is unfortunate because these drugs have valuable applications in veterinary medicine. Opium is the air-dried milky exudate obtained from the incised unripe seed capsules of the poppy plant, *Papaver somniferum*, which is indigenous to Asia Minor. The plant is cultivated in other countries, such as China, India, Iran, and Egypt. After the flower petals fall, the green seed capsule is incised. The milky juice dries on the capsule to form a brownish, gummy mass, which is collected, dried further, and powdered to make *Opium*, USP. Interestingly, morphine may be a ubiquitous component of plant-derived foods such as hay and lettuce. Its discovery has been reported in cow and human milk in concentrations of 200–500 ng/L (Hazum et al. 1981).

Pharmacologically, the active constituents of opium are alkaloids. Opium contains about 24 alkaloids but only 2, morphine and codeine, have much clinical use. The principal alkaloid of opium is morphine. A small fraction of opium contains thebaine (dimethylmorphine), another alkaloid, which has convulsant activity similar to strychnine.

OPIOID RECEPTORS. Opioid receptors have been identified within the central and autonomic nervous systems, the myenteric plexus of the gastrointestinal (GI) tract, heart, kidney, vas deferens, pancreas, fat cells, lymphocytes, and adrenal glands. These receptors are stimulated by opioids at the cell membrane surface in a stereospecific manner that has been described as a lock and key interaction. Opioid agonists have been described as "keys" that fit into a "lock," with only agonists being able to completely "turn in the lock" and produce a pharmacological response. A more complete description of the agonist-antagonist relationship is presented in the next section of this chapter.

The activation of the opioid receptor is coupled to changes in ion conductance and G-protein interaction. Opioid agonists with μ- or δ-receptor coupling will evoke G-protein-mediated inhibition of cAMP. This results in an increase in potassium conductance, hyperpolarization of neuronal membranes, and decreasing synaptic transmission. Kappa receptors have a similar G-protein-mediated mechanism, with resultant decreases in calcium influx and neurotransmitter mobilization and release. This decrease in calcium influx may partially explain the potentiation of opioid-induced analgesia by calcium entry blockers (Murkin 1991). It has been suggested that opioid agonists may produce a local anesthetic-like effect on the surface of excitable cells. Such an effect would not involve a stereospecific receptor (Frank 1985). Serotonergic pathways (Althaus et al. 1985) and GABA receptors (Bailey and Stanley 1994) may also play roles in the production of opioid-mediated analgesia. Opioids and α_2-adrenergic agonists are similar in their activation of inhibitory presynaptic adrenergic receptors on nociceptive fibers, but then exert their analgesic effects along different pathways. As a result, analgesia is enhanced and duration of analgesia is increased when α_2-adrenergic agonists and opioids are administered simultaneously.

Based upon studies in the chronic spinal dogs, W. R. Martin and coworkers in 1976 proposed the existence of three distinct types of opioid receptors. Each of these receptors was named for a drug that demonstrated high binding affinity for that receptor: μ (morphine), κ (ketacyclazocine), σ (SKF 10,047; *N*-allylnormetazocine). The δ receptor has since been identified, and subdivisions of the μ and κ receptors have been suggested. One of the κ subtypes may actually represent a new type of opioid receptor, the ε receptor (Nock et al. 1990). The μ, κ, and δ receptors are currently the most firmly recognized receptor classes (Pleuvry 1993).

Mu (μ) Opioid Receptor. Most of the effects of morphine-like drugs appear to be mediated by the μ opioid receptor. Two subtypes of this receptor have been identified (Wolozin and Pasternak 1981; Pasternak and Wood 1986; Itzhak 1988). The analgesic effects of morphine-like drugs are believed to be mediated by both the μ_1 and μ_2 subtypes, whereas the μ_2 subtype appears to mediate respiratory depression and inhibition of GI motility. The μ_1 subtype produces supraspinal analgesia and the μ_2 receptors produce spinal analgesia. Enkephalins appear to be the endogenous ligands for the μ_1 receptor, but endogenous ligands for the μ_2 receptor have not been identified.

Delta (δ) Opioid Receptor. The δ receptor shows the greatest selectivity for the enkephalin endogenous opioids. There are also opioid drugs that bind to δ receptors, and it has been suggested that the δ and μ receptors may exist as an interactive molecular complex (Vaught et al. 1982). The δ receptor appears to mediate analgesia primarily at the spinal level. There is some evidence to support two δ receptors; a δ_1, which is primarily involved in spinal pain modulation, and a δ_2, which is active supraspinally (Jiang et al. 1991; Mattia et al. 1991; Mattia et al. 1992)

Naloxone attenuates the decrease in blood pressure that occurs in shock, apparently by preventing δ-receptor activation by endogenous opioids released during shock (Holaday 1983a).

Large doses of naloxone are required to block δ receptors. Although naloxone is effective in reversal of shock, it also blocks the μ receptor, which mediates analgesia. This action of naloxone is not desirable in shock therapy because excruciating pain is intensified. A selective δ antagonist would be superior to naloxone in reversal of shock; such a selective antagonist, if it is eventually synthesized, will have the combined benefit of reversing the shock or cardiovascular depression without blocking opiate analgesia produced at non-δ receptors. Experimentally, a selective δ antagonist, ICI M 154129, will reverse such hypotension at doses that fail to antagonize morphine analgesia (Holaday 1983b).

Kappa (κ) Opioid Receptor. The κ receptor is involved in both spinal and supraspinal antinociception (Millan 1990). Both κ and μ receptors mediate analgesia, but the μ agonists produce euphoria and the κ agonists produce sedation and dysphoria. In addition, κ agonists produce naloxone-sensitive psychotomimetic effects (Millan 1990). The endogenous ligand for the κ receptor is probably dynorphin. Dynorphin is stored with vasopressin in the posterior pituitary. It appears to mediate an inhibitory feedback loop by activating κ receptors when released with vasopressin, preventing further release (Cox 1988). There is evidence of three κ-receptor subtypes. The κ_1 receptor is believed to mediate analgesia supraspinally, the κ_3 has spinal analgesic properties (Pasternak 1994), and it has been suggested that one of the subtypes may actually be the β-endorphin-specific ε receptor (Nock et al. 1990).

Sigma (σ) Opioid Receptor. The σ receptor was originally believed to mediate psychotomimetic effects of opioid agonist-antagonists, and opioids that produced such effects came to be known as sigma opioids. It is now understood that the drug originally used to characterize the σ receptor (SKF 10,047) is a racemic mixture of dextro- and levorotatory isomers that bind at least three types of receptors. The levorotatory isomers bind μ and κ opioid receptors, and the dextrorotatory isomers bind phencyclidine receptors and another receptor that was designated as σ (Musacchio 1990). The σ receptor exhibits a preference for dextrorotatory forms and is not sensitive to naloxone, which is a levorotatory form. The psychotomimetic effects of agonist-antagonists are mediated by levorotatory forms and can be antagonized by naloxone. This would apparently exclude the σ and phencyclidine receptors as mediators in production of opioid-related psychotomimetic effects. The σ receptors do not appear to mediate analgesic effects.

ENDOGENOUS OPIOIDS. Endogenous opioids are believed to exist in all vertebrate species and in many invertebrate species (Olson et al. 1981). Three families of endogenous opioids have been described: β endorphin, enkephalins, and dynorphin. The first, β endorphin, is produced from the precursor proopiomelanocortin, which cleaves to form adrenocorticotropic hormone (ACTH) and β lipotropin (Pasternak and Childers 1984). Beta lipotropin is devoid of opioid activity and cleaves further to yield β endorphin (Mains et al. 1977). The highest concentrations of β endorphin occur in the pituitary gland and in the medial, basal, and arcuate regions of the hypothalamus (Rossier et al. 1977). Beta endorphin also exists outside the central nervous system (CNS), in the small intestine, placenta, and plasma (Orwall and Kendall 1980; Houck et al. 1980). Proenkephalin is the precursor for methionine-enkephalin ([Met]enkephalin) and several other enkephalins (Gubler et al. 1981). Enkephalins are widely distributed in areas of the CNS which receive afferent nociceptive information (amygdala, globus pallidus, striatum, hypothalamus, thalamus, brain stem, and laminae I, II, and V of the dorsal horn of the spinal cord). [Met]enkephalin will rapidly depress ventilation and to a lesser extent heart rate and blood pressure when applied to the ventral surface of the brain stem in cats. These effects are naloxone-reversible (Florez et al. 1977). Enkephalins also exist in the peripheral nervous system (peripheral ganglia, autonomic nervous system, adrenal medulla), the GI tract, and plasma (Pasternak and Childers 1984). Dynorphin and leucine-enkephalin ([Leu]enkephalin) are derived from the precursor molecule prodynorphin. Dynorphins are believed to function primarily as neuromodulators in the CNS through interaction with μ, κ, and δ opioid receptors (Paquette and Young 1991) and may play a role in the central control of the cardiovascular system (Rochford et al. 1991). Dynorphin appears to be distributed throughout other areas of the CNS involved in nociception: periaqueductal gray, limbic system, thalamus, and laminae I and V of the dorsal horn of the spinal cord.

The endogenous opioids are part of a functional hierarchy that exists in nociception. Initial processing of afferent nociceptive information occurs from peripheral nerve endings to the dorsal horn of the spinal cord, areas in which both dynorphins and enkephalins are active. High concentrations of dynorphins, enkephalins, and β endorphin are found in key ascending and descending relay stations for nociception in the midbrain, brain stem, and thalamus. Dynorphin, enkephalin, and β endorphin are also associated with neurons in higher brain centers involved in the perception of pain (limbic system, amygdala, and cortex) (Bailey and Stanley 1994).

The greatest role of β endorphin is probably modulation of nociception during stress, midbrain periaqueductal gray stimulation, and acupuncture. Enkephalins act as inhibitory neurotransmitters and may elicit analgesia through the modulation of substance P release in the dorsal horn. Enkephalins may also play a role in acupuncture-mediated analgesia. Dynorphin may be more important in nociception at the spinal cord level through activation of κ receptors (Bailey and Stanley 1994), although current information suggests activity of κ receptors at both the spinal and supraspinal levels (Millan 1990). Other roles have been suggested for endogenous endorphins but are incompletely defined at this time.

OPIOID PHARMACODYNAMICS. When the pharmacodynamics of opioids is discussed, several terms must be defined and explained.

Affinity describes a drug's ability to bind to its receptor sites within the body. A drug with a high affinity will bind readily and strongly to those receptors. Conversely, a drug with no affinity for a specific receptor will not interact with that receptor at all.

The *activity* of a drug describes its ability to cause an action in or on the cell where its receptor resides. A drug with no activity will have no direct effect even if it is bound to a receptor for which it has a high affinity.

In the case of opioids the *potency* of a drug is often directly related to its affinity for opioid receptor sites. This means a drug can be described as very potent (high affinity) even if it exhibits little or no activity when bound to a receptor. This terminology can be confusing since the potency of an opioid is often assumed to be an indication of its analgesia-producing ability.

The *efficacy* of an opioid is a better indication of its analgesic properties. The efficacy of a drug can be illustrated using a dose-response curve (Fig. 13.1). On a dose-response curve the drug that produces the most analgesia, as evidenced by the height at the right end of the curve, is the most efficacious. If two drugs have equal activity at a receptor site, the drug with the higher affinity is the most potent. Alternatively, the opioid with the greater activity is the more efficacious when two drugs with equal affinity are compared.

If the activity of opioids was limited to one receptor type, the relationship between efficacy, activity, and potency would be straightforward, but this is not the case. The affinity and activity of an opioid can vary between receptor types, and this results in many variations in overall analgesic efficacy. In an attempt to describe this relationship, the opioids are often categorized as to their affinity and activity into full agonists, full antagonists, partial agonists, and agonist-antagonists.

Full Agonists. These opioids have both affinity for and activity at all the clinically relevant receptors. The full agonists are known for their ability to produce profound analgesia as well as significant side effects such as respiratory depression. Morphine is an example of a full agonist. The dose response curve for a full agonist is shown in Fig. 13.1A.

Full Antagonists. These opioids have affinity for but no activity at opioid receptors. The antagonists are used as reversal agents for agonists because they have no significant analgesic properties (Fig. 13.1B). To effectively reverse the agonists they must bind to the receptors and block access by the agonists. This can be done by using an antagonist with a higher receptor affinity than the agonist or using a larger dose of antagonist. Administration of an antagonist after an agonist results in a shift of the dose-response curve of the agonist to the right. This means the agonist dose needed to produce a specified level of analgesia is now greater. These drugs are often used clinically to reverse the effects of a full agonist. The goal is to reverse the agonist's undesirable effects, but unfortunately it is not possible to selectively leave the analgesia unaffected. Careful titration of the antagonist dose can, however, result in some residual analgesia. These drugs are competitive antagonists, meaning they are competing with the agonist for a limited number of receptor sites.

Partial Agonists. Partial agonists have affinity for only some opioid receptors, and they have significant activity for the receptors they do interact with. But there are other opioid receptors where they have no affinity or activity. The efficacy of these drugs is limited when compared to the full agonists since they cannot involve all the receptor types in pain control. As a result, the initial portion of their dose-response curve is similar to that of the full agonists, but the maximal analgesia produced is less (Fig. 13.1C).

Agonist-Antagonists. Classically, these opioids are described as having affinity for all opioid receptors but only demonstrating agonist behavior at some of them; they were thought to act as antagonists at the other opioid receptors. More recently there is increasing evidence that they may have some very weak agonist activity at the receptors where they were previously thought to be antagonists (Bowdle and Nelson 1994). But this activity is of such low magnitude that they are unable to produce the degree of analgesia associated with the full agonists. The dose-response curve of an agonist-antagonist indicates a lower maximal efficacy (Fig. 13.1D). The agonist-antagonists effectively act as antagonists at receptors where they show affinity but have little to no activity when they are administered with full agonists since they shift the dose-response

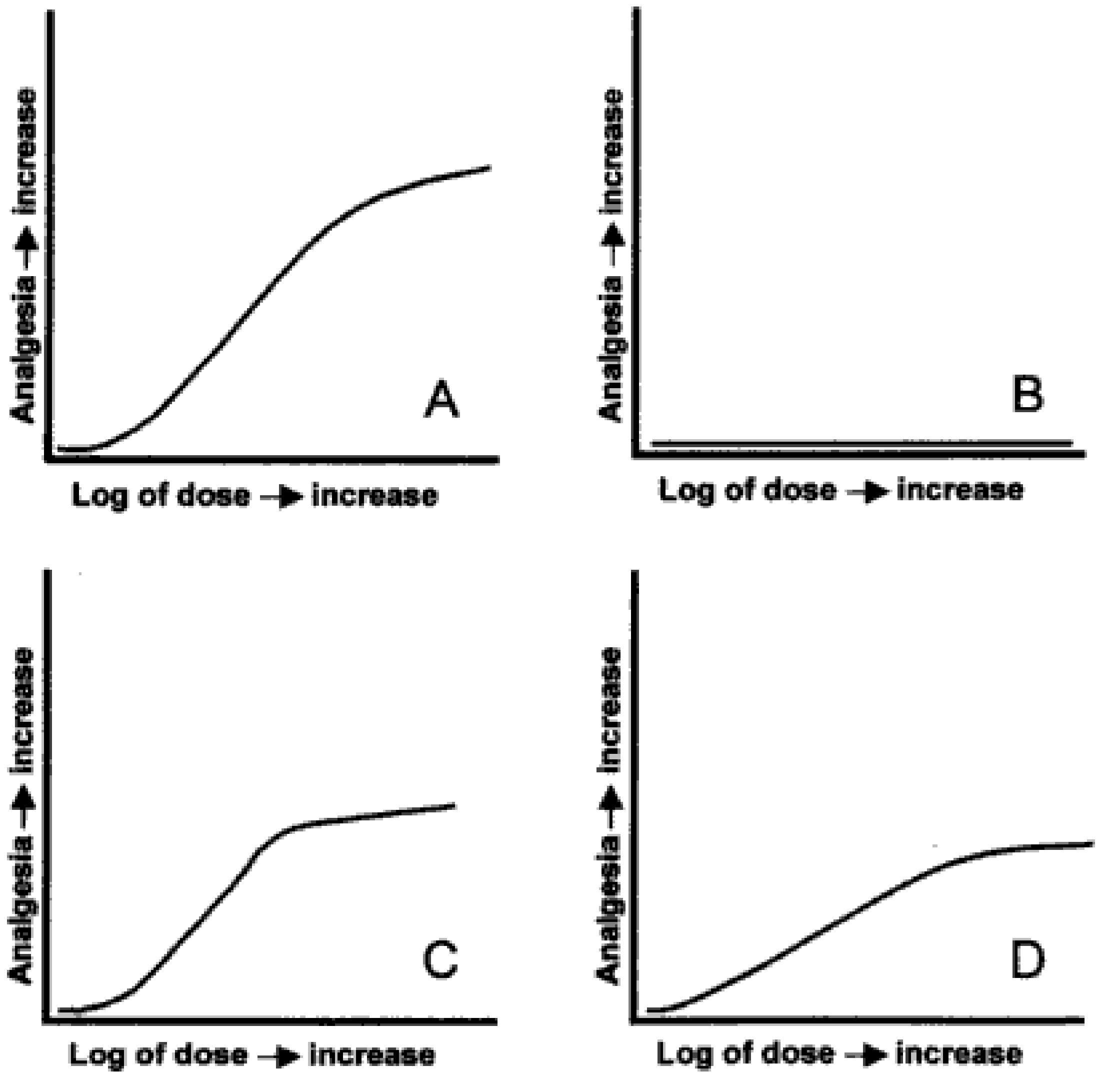

FIG. 13.1.—Four dose-response curves for different types of opioids. The horizontal axes are the log of the dose and the vertical axes are the amount of analgesia produced. (A) A full agonist type opioid such as morphine. (B) A full antagonist type opioid such as naloxone. (C) A partial agonist type opioid such as buprenorphine. (D) An agonist-antagonist type opioid such as butorphanol.

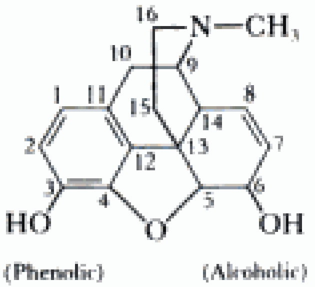
curve of the agonist to the right. Clinically, these agents can be used to partially reverse the effects of the full agonists. With them it is somewhat easier to provide partial reversal with some analgesia remaining because of their own, albeit weaker, intrinsic analgesic properties.

OPIOID AGONISTS

Morphine Sulfate. Morphine was the first of the plant alkaloids to be isolated. It was crystallized from crude opium by F. W. A. Sertürner in 1805. *Morphine Sulfate,* USP, is the principal salt of morphine. Pharmacopeias generally base the standard for opium upon its morphine content. The *United States Pharmacopeia* states that official powdered opium shall contain not less than 10% nor more than 10.5% of anhydrous morphine. In addition to the alkaloids, opium contains pharmacologically inert substances such as organic acids, resins, gums, and sugars, which constitute about 75% of the weight of dried powdered opium.

CHEMISTRY. The morphine molecule consists of a partially hydrogenated phenanthrene nucleus, an oxide link, and a nitrogen-containing structure (ethenamine, —CH_2CH_2—NCH_3). In addition, two hydroxy groups (alcoholic and phenolic; see Fig. 13.2) are important in maintaining the pharmacologic integrity of the morphine molecule.

Synthesis of morphine has been accomplished with considerable difficulty. Semisynthetic derivatives are relatively easy to manufacture by substitution of chemical radicals in place of the hydrogen atoms at one or both hydroxy positions of the morphine molecule. Chemical relationships of the natural and semisynthetic opiates are given in Table 13.1.



Morphine

FIG. 13.2

TABLE 13.1—Natural and semisynthetic opiates

Drug	Phenolic position	Alcoholic position
Morphine	H	H
Methylmorphine (codeine)	CH_3	H
Hydromorphone*	H	O
Diacetylmorphine (heroin)	$COCH_3$	$COCH_3$
Oxymorphone†	H	O

*Hydrogenation of carbons 7 and 8 occurs with the double bond being removed; an oxygen atom replaces the H and OH groups in position 6.

†With exception of an OH group replacing the H atom in carbon 14 position (opposite or to the left of carbon 8), the chemical structure is identical to hydromorphone.

When substitutions are made in place of one or both hydrogen atoms at the phenolic and alcoholic hydroxy position, pharmacodynamic activity of the morphine molecule is altered in an interesting manner. Alteration of the phenolic hydroxy group reduces analgesic potency, respiratory depression, and the likelihood of constipation. A stimulant activity upon the CNS is noted when substitution is made in this position. The lessened analgesic potency and increased stimulant effect typify the pharmacodynamic activity of codeine. If substitution is made at the alcoholic hydroxy position, narcotic and respiratory depression are enhanced. Consequently, hydromorphone hydrochloride is more potent as an analgesic agent than morphine. Substitution in either of the hydroxy positions lessens emetic activity of the parent molecule. As a result, both codeine and hydromorphone are less potent than morphine in producing emesis.

Other semisynthetic derivatives of morphine are apomorphine hydrochloride, a potent emetic agent, and naloxone hydrochloride, an antagonist of opiate-type drugs that has important clinical application.

To date thousands of opioid analgesics with diverse chemical structures have been synthesized and studied for their analgesic, antidiarrheal, antitussive, and addicting characteristics (Martin 1984). Consequently, many analgesics have been discovered that have been classified as either opiates or morphine-like drugs. The morphine-like drugs generally differ from morphine in their pharmacologic actions.

PHARMACOLOGIC ACTIONS. The pharmacologic actions of morphine are described below in great detail and are similar to the general effects of all the opioids. The specific organ effects of the other opioids are not described as thoroughly since they are generally similar to those of morphine.

BRAIN AND SPINAL CORD. The action of morphine upon the brain and entire CNS is irregular. It appears that the brain contains at least three distinct opioid nerve networks: an enkephalin system with components similar to those found in the adrenal medulla, a β-endorphin system, and a dynorphin system (Watson et al. 1982). The enkephalin system appears to be a separate entity from the β-endorphin and dynorphin systems. Immunochemically, dynorphin occurs in neurons, while enkephalin does not.

The basis of irregular action attributable to morphine can be better understood now that different types of opioid receptors have been identified. The major pharmacologic action of morphine is produced almost exclusively by the (−) enantiomer or isomer. The unnatural (+) enantiomer of morphine induces only minimal activity.

Early CNS effects of morphine administration in animals include changes in behavior (Simon and Hiller 1978). CNS depression is seen in the dog, monkey, and human, while CNS stimulation or excitatory behavior is elicited in the cat, horse, goat, sheep, pig, and cow following systemic administration of morphine. In an effort to ascertain whether the species difference in behavior induced by morphine is a reflection of the distribution pattern of opiate binding sites in the brain, Simon (1977) investigated binding of radiolabeled etorphine in various regions of the brain in a number of species. There is reasonably good reproducibility of binding level for any given anatomical region in the dog, monkey, human, sheep, cow, and cat. The only areas of the CNS that show consistent differences are the amygdala and frontal cortex. These regions are at least two times higher in receptor level for the species that show CNS depression than for the species that show CNS excitation to opiates (Simon 1977). These consistent differences between the two groups of mammals are most baffling. The amygdala and frontal cortex are components of the limbic system wherein most of the areas of high opiate binding in dog, monkey, and human are located (Simon 1977). Interestingly, monkeys become placid following bilateral amygdalectomy, whereas the cat displays a sustained aggression and ferocity. Consequently, amygdalectomy resembles the effects seen in acute morphine administration in these two species.

Considerable controversy has existed regarding whether morphine should be used in the cat because of its inability to consistently produce sedation. Studies indicate that morphine sulfate is effective in obtunding intense pain. According to Davis and Donnelly (1968), the excitatory response frequently observed in the cat may be the effect of overdosage with morphine. When doses of morphine hydrochloride of 5, 10, and 20 mg/kg are injected intraperitoneally in conscious cats, a manic response characterized by hyperexcitement and aggressive behavior is observed (Dhasmana et al. 1972). This response can be prevented by pretreatment with either CNS catecholamine depletors (i.e., reserpine, tetrabenazine) or central dopaminergic receptor blocking agents such as those produced by chlorpromazine hydrochloride and haloperidol, which also have α-adrenergic receptor blocking action. Another interesting action of morphine in the cat is the production of insomnia, which is reversible by naloxone. If β endorphin or morphine is injected intraventricularly, insomnia is produced (King et al. 1981).

The CNS excitation or manic effect induced by morphine in the cat may occur from alteration in the functioning of brain dopaminergic or noradrenergic systems. It is known that drugs that block dopamine receptors always increase striatal dopamine synthesis and turnover. This is also true with morphine (Lal 1975). Brain concentration of homovanillic acid, a metabolite of dopamine, increases following morphine, suggesting that an increase in catabolism occurs in brain dopamine. Conversely, morphine depresses noradrenergic activity in the locus ceruleus of the rat, and this effect appears to be related to the unavailability of norepinephrine at the receptor sites. It is possible that stimulatory action of morphine and related compounds, including fentanyl, is due to indirect action of these drugs, predominantly on noradrenergic cerebral functions (Fidecka et al. 1978). If this is correct, it may explain the inhibitory effect of reserpine on stimulatory actions of morphine and fentanyl. Reserpine does not inhibit synthesis of dopamine but does inhibit activity of dopamine-β-hydroxylase, making interaction between the enzyme and dopamine more difficult. Consequently, reserpine decreases the rate of synthesis of norepinephrine. Increased locomotor activity or persistent restlessness (stereotypy) seen after morphine administration appears to be due to release of norepinephrine and not dopamine.

As stated, swine, goats, sheep, cattle, and horses are generally stimulated by morphine. However, effects of morphine in the horse and the ox are somewhat irregular. In these species it may be that the dosages used are higher than required to produce analgesia similar to that observed in the cat. Moreover, increased turnover of dopamine or increased release of norepinephrine following morphine administration may also be involved in production of restlessness and CNS excitation in these species similar to that in the cat. If this is true, dopaminergic and noradrenergic blocking agents such as the phenothiazines or droperidol should effectively prevent excitation as it does in cats. Since the phenothazine-derivative tranquilizers such as chlorpromazine and acepromazine induce arterial hypotensive effects, their use for this purpose is potentially dangerous.

CNS depression does not necessarily need to occur prior to or concomitantly with development of the state of analgesia. Morphine is capable of producing a high degree of analgesia without accompanying CNS or respiratory depression in animals such as the hamster. Perhaps the hamster has few or lacks entirely the μ and δ opioid receptors that mediate the respiratory depressant effects of opiates. It is possible that the hamster could have a higher density of σ opioid receptors that mediate an increase in the respiratory rate.

In addition to known analgesic effects following intracerebral administration of enkephalins or morphine, long-lasting electrographic seizures occur in most animals. In the rat, analgesia occurs after injections of methionine-enkephalin into or near the ventral, caudal midbrain periaqueductal gray matter. Epileptiform seizures and other electroencephalographic disorders are seen with enkephalin injections into or near the forebrain dorsomedial nucleus of the thalamus. Seizures are accompanied by myoclonic twitches, catalepsy, muscular rigidity, and "wet-dog shakes" and are blocked by prior administration of naloxone (Frank et al. 1978). These effects suggest that enkephalin-induced analgesia and seizures are mediated by opioid receptors located in different regions of the brain that are pharmacologically different. Now that it is known that the σ opioid receptor mediates mania and that dynorphin induces a wide spectrum of motor effects via the κ receptors, these receptors may be involved.

Crib biting, often referred to as a vice in horses, probably is better described as a stereotypy (Dodman et al. 1987) or an aberrant type of motor behavior. It is interesting that Dodman and associates have found that narcotic antagonists (naloxone, naltrexone, others) will prevent crib biting. Its prevention by narcotic antagonists is evidence that this form of stereotypy involves activation of opioid receptors, possibly by release of endogenous opioids in the CNS (Dodman et al. 1987).

Interestingly, laboratory animals with only the spinal cord intact will show strychnine-like tetany following administration of morphine. This cord-stimulating activity, as well as increased central seizures, is the reason that morphine is strictly contraindicated in treatment of strychnine poisoning. The CNS and cord stimulant effects of morphine strongly suggest that it should be contraindicated in treatment and control of epilepsy in dogs and cats. The author has induced convulsive seizures in the dog and rabbit with large doses of morphine (500 mg/kg).

Ability of opiates to evoke generalized convulsive seizures is well recognized and, for the most part, has been considered to be an undesirable side effect (Martin 1984). Opioids appear to exert both convulsant and anticonvulsant activity through several modes of action and probably through a number of receptor mechanisms.

The dog shows a brief preliminary period of central excitement marked by restlessness, panting, salivation, nausea, vomiting, urination, and defecation. These symptoms gradually disappear and are followed by a stupor indicating depression of the cerebral cortex. Inasmuch as morphine induces CNS depression and accompanying analgesia in the dog, clinicians have used it almost entirely in this species. Of the opiate derivatives, morphine is preferred by clinicians primarily for preanesthetic medication in the dog over its use in other animals because the drug facilitates handling for induction of general anesthesia.

Information on effectiveness of morphine in relieving pain comes primarily from use of the drug in human patients because of the ease of noting the subjective response. Morphine will relieve pain without blocking motor activity or consciousness. The pain threshold is increased so that moderate pain disappears and sharp pain is dulled. Morphine is most useful in humans in relieving pain arising from the viscera and from trauma. Anxiety and alarm disappear. Sleep may be produced during the period of morphine analgesia. In human patients, morphine is used almost exclusively for relief of pain. These observations give some indication as to the probable effectiveness of morphine in relieving pain in animals.

EMETIC CENTER. Considerable species variation occurs with respect to effect of morphine upon vomiting in animals; e.g., swine and chickens do not respond to central-acting emetics (morphine, apomorphine) but do respond to local emetic agents (copper sulfate, zinc sulfate). It is interesting that apomorphine stimulates dopamine receptors (dopamine agonist), whereas morphine does not. Morphine blocks emetic action of apomorphine.

Both dogs and cats will respond to central- and local-acting emetics. However, the cat requires considerably higher doses of morphine or apomorphine to induce vomiting than the dog. For example, morphine and apomorphine dosages 740–2800 times greater are required in the cat over the level that stimulates vomiting in the dog (Brand and Perry 1966). Horses and ruminants do not vomit following administration of central- or local-acting emetics. The emetic center in the dog is readily stimulated by small to moderate dosages of morphine. Within 5–10 minutes after subcutaneous (SC) injection of morphine, most dogs will vomit profusely unless the stomach is empty, in which case only saliva and bile may be lost. The act of vomiting is preceded by salivation and nausea and is usually accompanied by defecation.

A trace of morphine applied directly to the floor of the fourth ventricle will produce simulated vomiting in dogs from which the entire GI tract has been removed. This effect would seem to exclude gastric irritation as a causative factor as has been previously believed.

COUGH CENTER. The cough center appears to be more susceptible to morphine than other medullary centers. Morphine is an excellent cough sedative, and were it not for its addictive properties to dogs as well as humans, the drug probably would be the most widely used and effective control available for dry, nonproductive coughs. Generally, morphine is used only in those patients for whom codeine previously was ineffective.

THERMOREGULATION. A variation in effect upon body temperature is seen in different species following administration of morphine. Hypothermia is the dominant body temperature response to morphine in rabbits, dogs, and monkeys, whereas hyperthermia usually occurs in cats, goats, cattle, and horses (Oka 1978). In guinea pigs, rats, and mice, low dosages of morphine elicit a hyperthermic effect, while higher dosages induce hypothermia. The hypothermic action of morphine wanes in rabbits following repeated or chronic administration. In monkeys and rats not only is the hypothermic action of morphine reduced following repeated administration but hyperthermia becomes the dominant response.

Morphine accelerates release of 5-hydroxytryptamine (serotonin) from the serotonergic neurons in the hypothalamus (Oka 1978). Release of serotonin stimulates warm-sensitive interneurons and/or inhibits cool-sensitive interneurons in the hypothalamus. Activation of warm-sensitive neurons stimulates heat-dissipation responses, and inhibition of cool-sensitive neurons depresses the heat-production responses. Stimulation of the heat-loss pathway and/or inhibition of the heat-production pathway result in a drop in body temperature (Oka 1978).

Morphine-induced hypothermia is abolished following serotonin depletion with parachlorophenylalanine (an inhibitor of tryptophan 5-hydroxylase). Administration of 5-hydroxytryptophan, a precursor of serotonin, to animals pretreated with parachlorophenylalanine restores the typical hypothermic response to morphine, meperidine, and methadone. Hypothermia (also catalepsy) induced by opiates is antagonized by thyrotropin-releasing hormone (TRH); TRH does not affect the analgesic effects of the opiate-type drugs (Zaloga et al. 1984). Although TRH does not bind to opioid receptors, it is referred to as a physiologic opiate antagonist (Bernton et al. 1985).

In the cat, IV injection of morphine (1–10 mg/kg) induces a dose-related hyperthermic response (Clark and Cumby 1978). Administration of metiamide (an H_2-histamine-receptor blocking agent) or indomethacin (prostaglandin synthetase inhibitor) does not antagonize morphine-induced hyperthermia in the cat. This indicates that histamine and prostaglandins are apparently not required for the hyperthermic effect induced by morphine (Clark and Cumby 1978).

The morphine antagonist (naloxone) does not prevent febrile responses in cats to leukocytic pyrogen (Clark and Harris 1978). This implies that endogenous opioid peptides (enkephalins) that are antagonized by naloxone are not likely to mediate febrile responses to pyrogens. The cerebral ventricular administration of methionine-enkephalin induces both hyperthermia and emesis in cats (Clark 1977). Pretreatment with naloxone reduces the hyperthermic response and prevents the emetic response of methionine-enkephalin in the cat.

Panting is noted initially in the dog after administration of morphine but finally stops with a decline in body temperature. Sweating and hyperglycemic response in the horse following administration of morphine is believed to be associated with increased circulating level of epinephrine.

Although apomorphine is a semisynthetic derivative of morphine, it induces hyperthermia in rabbits but not the hypothermia seen following administration of morphine. Apomorphine is well established as a dopaminergic agonist. Dopamine is one of a number of catecholamines found in the brainstem that have a thermoregulatory role in the rabbit. Experimental evidence exists indicating that central dopaminergic mechanisms are activated prior to a temperature response in animals following administration of *d*-amphetamine or apomorphine; both these drugs induce hyperthermia, and the hyperthermic response can be blocked by a dopaminergic receptor blocking agent such as pimozide or haloperidol.

In some species (mice, rats), apomorphine elicits hypothermia. Dopamine-receptor blocking agents such as pimozide and haloperidol are able to competitively antagonize hypothermia induced by apomorphine (DiChiara and Gessa 1978).

EYE. Morphine produces a variable effect upon the size of the pupil in animals. Morphine causes mydriasis in the monkey, cat, sheep, and horse and causes miosis in dogs, rats, rabbits, and humans. The dog is less sensitive to the miotic action of morphine than humans (Martin 1984). Over 2 mg/kg morphine administered parenterally is required to induce maximum miosis in the dog.

The iris of the bird is not affected because it contains nonresponsive skeletal muscles. Although morphine activates parasympathetic input (i.e., increases the spontaneous firing rate of light-sensitive neurons recorded from the anterior oculomotor nucleus) to the iris, the miotic effect is antagonized by increased catecholamine release from the adrenal glands; this results in mydriasis (Wallenstein and Wang 1979). Adrenalectomy or administration of phenoxybenzamine antagonizes the mydriasis induced by release of catecholamines in the cat, and miosis is observed.

Since the σ receptor mediates pupillary dilation, the variation in response induced by morphine upon the eye in different species may be related to the density or number of σ receptors within the oculomotor nucleus.

RESPIRATORY SYSTEM. The respiratory center of the dog is initially stimulated; panting is seen and is attributable to the initial rise in body temperature. As body temperature declines and CNS depression increases, respiratory activity is depressed by morphine, resulting in decreased minute volume of respired air. The threshold of response to carbon dioxide stimulation is increased and the alveolar concentration of carbon dioxide is higher. Respirations become slower and shallower. In deep sedation, Cheyne-Stokes type respiration may occur.

The agonistic effects of morphine upon μ_2, and σ opioid receptors can result respectively in either depression or stimulation of respiratory activity. Depressant or stimulatory activity upon respiration is dependent upon the dose of morphine administered and can also vary within the various animal species.

In normal, healthy dogs, small doses of morphine may not decrease respiratory minute volume and oxygen consumption by more than about 10%. Following large doses of morphine that lead to convulsive seizures, respiration rate is markedly increased. Eventually, depression and paralysis of the respiratory center develop, ostensibly from overstimulation. Moreover, moderate to large doses are known to produce bronchiolar constriction in the dog. Significant bronchoconstriction occurs following an IV dose of 1 mg/kg, and a more marked effect is produced following a dose of 2.5 mg/kg; a decrease in lung capacity at the latter dose averaged 24% (Shemano and Wendel 1965).

CARDIOVASCULAR SYSTEM. Although opiate peptides were initially associated with regulation of pain, they appear to have importance in regulation of the cardiovascular system. They are particularly important in its central neural control (Holaday 1983).

In the conscious dog, morphine (2 mg/kg) administered intravenously induces a substantial degree of coronary vasoconstriction, reduction in coronary blood flow, and increase in coronary vascular resistance (Vatner et al. 1975). Interestingly, coronary vasoconstriction is not seen after α-adrenergic blockade; morphine apparently has an indirect α-adrenergic stimulating action, since it stimulates release of catecholamines.

In the anesthetized dog, morphine (0.5 mg/kg) administered intravenously induces a transient drop in arterial pressure and a concomitant increase in heart rate (DeSilva et al. 1978a). Arterial pressure soon returns to base line or control levels following administration of morphine. As arterial pressure returns to normal to slightly elevated levels, heart rate decreases appreciably from increased pressoreceptor activity as well as from a vagotonic effect of morphine. Due to its vagotonic and sedative actions, morphine exerts significant protective effect on increased ventricular vulnerability to fibrillation (DeSilva et al. 1978b).

Effects of morphine in humans are in marked contrast to dogs. Coronary blood flow is increased and a slight coronary vasodilation occurs in humans (Leaman et al. 1978). Although morphine has been used satisfactorily for years in treatment of human patients with cardiac disease (e.g., acute pulmonary edema from left heart failure, pain relief following acute myocardial infarction), its use in the dog for treatment of cardiopulmonary complications (e.g., "cardiac dyspnea") may not, as originally thought, have therapeutic merit. Use of morphine in such cases may be imprudent.

URINARY TRACT. The initial effects of morphine along with salivation, nausea, vomiting, and defecation may also include urination. As the effect progresses, morphine can decrease urine secretion in the dog to 10% or less of normal by liberating an excess of the antidiuretic hormone from the pituitary gland. This hormone, in excess, stimulates intensive reabsorption of the glomerular filtrate by the cells of the renal tubules. To produce such a response, the dose of morphine must approach 2.4 mg/kg intravenously or 5 mg/kg subcutaneously.

There is evidence that dynorphin, an opioid peptide, may be released concomitantly from the pituitary with the antidiuretic hormone (i.e., vasopressin). With the presence of opioid receptors in the kidney, it is also logical to expect a direct action of inhibition of prostaglandin activity.

Morphine increases muscular tone of the bladder, which, among other effects, results in spasm of the sphincter, which may make urination difficult. Conversely, animals seem to be less affected and have less difficulty in this respect than humans.

GI TRACT. Emptying the GI tract is the dog's first response to morphine. Following the initial emptying, morphine causes constipation of the dog and other animals. The GI tract appears to contain both μ and δ opioid receptors. Activation or stimulation of either receptor results in inhibition of GI tract motility. This action is the basis for using opiate-type antidiarrheal agents for control of diarrhea.

Since it has been postulated that all peptide hormone-producing cells are derived embryologically from the neural ectoderm, it should not be too surprising to learn of the presence of brain peptides in the GI tract (Guillemin 1978); e.g., opioid receptors are present in the myenteric plexus of the GI tract. Enkephalins and substance P have also been identified in association with opioid receptors in the GI tract. Stimulation of opioid receptors in guinea pig ileum leads to constipation (Knoll 1977).

Morphine has a persistent spasmogenic effect upon intestinal smooth muscle by a direct action, partly by a cholinergic and partly by a histaminergic mechanism (Türker and Kaymakcalan 1971). Atropine partially inhibits the spasmogenic effect of morphine. Mepyramine partially blocks or antagonizes spasmogenic activity of morphine; apparently this is related to its histamine-releasing action. Release of serotonin occurs in the isolated intestine of the dog when it is perfused with morphine.

By virtue of the persistent spasmogenic action, the primary effect of morphine is to increase tonus of smooth muscles of the entire GI tract. The sphincters exhibit a spastic tonus. The propulsive motility of the tract is markedly depressed, apparently as a result of excessive tonus that interferes with normal peristaltic waves. The tonus may become great enough to close or constrict the intestinal lumen in the conscious dog. Thus passage of food through the tract is delayed. The delay results in increased absorption of water from the ingesta, which contributes to constipation. Tonus of the anal sphincter is increased by morphine. In addition, morphine depresses mental perception of ordinary sensory stimuli for the defecation reflex.

The effect of morphine upon enzyme secretions of the digestive tract of the dog is variable but slight. Biliary secretion appears to be reduced to one-third of normal. Morphine causes an initial delay in gastric secretion of HCl, which is later compensated by excessive secretion.

ENDOCRINE SYSTEM. Exogenous and endogenous opiates induce an array of effects upon pituitary hormone release in both animals and humans (Morley 1981). In the rat, opiates stimulate release of growth hormone, ACTH, and prolactin; they also inhibit release of glycoprotein hormones. In humans, endogenous opiates appear to be important in the physiologic regulation of ACTH and gonadotropin release. Paradoxically, the inhibitory release of ACTH in Cushing's disease suggests a potential use of specific and long-acting opiate antagonists in treatment of this condition (Morley 1981).

Opiates exert an important modulating action upon the hypothalamus; additional modulating effects may occur at the pituitary and upon target organs. Opiate-induced endocrine actions appear to be mediated through dopaminergic and/or serotoninergic mechanisms (Morley 1981).

IMMUNE SYSTEM. An interaction between the immune system and central neuroendocrine mechanisms has been suspected for a long time (Joseph et al. 1985). The nonspecific influence of the pituitary-adrenal axis upon the immune system by altering or increasing resistance to infectious diseases has been recognized from the time of the Hans Selye era of stress research.

Recent discoveries have resulted in identification of corticotropin-releasing factor (CRF), as well as the simultaneous secretion of ACTH and β endorphin, from the pituitary during stressful conditions (Plotnikoff and Murgo 1985). This has led to identification of interactions among the stress hormones (CRF and enkephalins-endorphins) as well as thymus hormones and even interferons, ACTH, and endorphins at the peripheral level of the lymphocyte. Viral infection of lymphocytes induces the cells to synthesize Ir ACTH and Ir endorphins (Blalock and Smith 1985).

In summary, it appears that the immune and neuroendocrine systems have the capability of signaling each other through common or related peptide hormones and receptors. Enkephalins and endorphins can be considered immunomodulators and modifiers of the physiologic response and may have important application in immunotherapy (Wybran 1985).

ABSORPTION, FATE, AND EXCRETION. Morphine is a weak acid; it has a pK_a of 8.0, which means it is poorly ionized at physiological pH. In humans it is 20–40% protein bound, the elimination half-life is 2–4 hours, the steady-state volume of distribution (Vd) is 3–5 L/kg, and the clearance rate is 15–30 mL/min/kg (Bailey and Stanley 1994).

Morphine is absorbed from the small intestine and some may be absorbed from the stomach. The absorption from the GI tract is somewhat variable, with a large individual variability (Dohoo and Tasker 1997). It is absorbed promptly following SC injection. Morphine is not absorbed through intact skin, but a scarified epithelium permits slow entrance to the circulation.

Biotransformation of morphine to morphine-3-glucuronide is the primary metabolic pathway for inactivation and eventual elimination of the drug (Sanchez and Tephly 1974). The principal catalyst in formation of morphine glucuronide is a hepatic microsomal uridine diphosphate (UDP)-glucuronyl transferase, which transfers a glucuronic acid moiety from UDP-glucuronic acid (UDPGA) to morphine. Other metabolites are formed as well, some of which are pharmacologically active. The most prevalent of these is morphine-6-glucuronide (Christrup 1997). With the exception of the cat, approximately 50% of morphine administered to most mammals appears in the urine as the glucuronide form. In the cat, a deficiency in UDPGA and its associated glucuronyl transferase enzyme does not favor glucuronidation of morphine. Increased toxicity of aspirin and salicylate drugs is linked to failure of the cat to conjugate the compounds with glucuronic acid. The biologic half-life of morphine would be expected to be longer in the cat because of its inability to form glucuronides. Surprisingly, the biologic half-life in plasma is only 3.05 hours in the cat following SC injection of morphine (1 mg/kg) (Davis and Donnelly 1968). The biologic half-life of morphine in other species is probably shorter than in the cat; these values were not located in the literature.

In humans, morphine was studied after a single IV dose (10 mg/70 kg); a rapid initial decline of morphine in the blood occurred during the first 6 hours after administration (Spector and Vesell 1971). After rapid initial decline of the drug, levels of morphine could be detected in blood for several hours; this may be attributable to enterohepatic recirculation, persistence of metabolites, or a combination of these and other factors. During the first 6 hours, the half-life of morphine ranged from 1.9 to 3.1 hours. Following this, disappearance of the drug was slow, with a half-life of 10–44 hours (Spector and Vesell 1971).

In horses, morphine can be found in serum samples for at least 24 hours after an IV injection of 0.1 mg/kg; it is present in urine for up to 144 hours (Combie et al. 1981).

TOXICITY. Newborn animals are known to be more sensitive to morphine than adults (Auguy-Valette et al. 1978). Morphine-induced toxicity decreases with maturity of the animal. This is associated with decrease in the capability of morphine to enter the brain commensurate with development of the blood-brain barrier.

The toxic dose of morphine for the dog appears to be variable. Subcutaneously or intravenously, the fatal dose is 110–220 mg/kg. Convulsive seizures quite similar to strychnine occur in most species following administration of higher doses of morphine. Thebaine (dimethylmorphine), a component of opium, is also well known for its strychnine-like seizures.

In the small rodent (mouse), acute toxicity and death from morphine are produced by IV administration of 221–311 mg/kg; an SC dose between 420 and 526 mg/kg produces death. Young swine apparently are quite susceptible to the stimulant action of morphine.

Addiction is rarely encountered in animals because narcotic drugs are not ordinarily administered for prolonged periods. There is a clinical report of addiction from prolonged (6–8 months) use of paregoric (camphorated tincture of opium) in the dog by an overzealous owner (Segall 1964).

With discovery of β-endorphin and opioid receptors, the most exciting outgrowth from this research could be the prospect that endorphin deficiency might play some role in narcotic addiction. A hypothesis has been advanced by Goldstein (1976) that classical hormonal feedback mechanisms might act to inhibit or suppress endogenous opioid synthesis (i.e., β endorphin) when receptors are occupied by an exogenous opiate like morphine. Sudden withdrawal of the exogenous substance can expose the deficiency in endogenous synthesis (compare the adrenal crisis if corticosteroid administration is abruptly stopped); thus induced endorphin deficiency might play a role in the immediate or protracted abstinence syndrome (addiction). It would be most interesting if this postulated disease entity proved to be an endorphin deficiency.

PRECAUTIONS AND CONTRAINDICATIONS. Morphine should be used with care in acutely uremic and toxemic dogs. By stimulating secretion of the antidiuretic hormone, morphine increases reabsorption of the renal filtrate. A large dose of morphine may decrease urine flow in the dog by 90%.

Morphine cannot be used to control convulsive disorders such as strychnine poisoning, tetanus, and epilepsy. It should not be administered to dogs suffering from traumatic shock because of its immediate hypotensive effect upon arterial pressure. This is important if provisions are not available to expand the blood volume and restore systemic arterial pressure.

Opiates must not be used in animals with head injury. This use results in an increase in intracranial pressure due to a decreased sensitivity to arterial carbon dioxide partial pressures (Heidrich 1985).

In large animals, opiates should be used cautiously. Overdoses can result in prolonged periods of restlessness and excitement.

CLINICAL USES. Morphine has been used for a wide variety of clinical conditions since the beginning of recorded history. Several of these uses are still valid. When an opiate is used to relieve pain or control diarrhea or coughs, only symptomatic therapy is administered. The underlying etiology and pathology are still present. Furthermore, unwise use of opiates may obscure symptomatic progress of disease.

DOGS. Morphine is important in canine surgery to relieve pain, facilitate handling the patient for local or general anesthesia, and decrease the amount of CNS depressants necessary to produce surgical anesthesia. The peak effect of morphine is usually reached between 30 and 45 minutes following SC injection. Duration of the analgesic effect has not been accurately determined but appears to last 1–2 hours. The SC doses of morphine recommended for preanesthetic medication vary from 0.1 to 2 mg/kg. For inducement of analgesia in the dog, an IV, IM, or SC dose of 0.25–0.5 mg/kg is generally recommended.

Onset of action after an IM or SC injection is within a few minutes. Atropine (0.045 mg/kg) is routinely administered by the SC or IM route at the same time as morphine to prevent salivation and bronchial secretions. Very young, aged, and debilitated dogs are more susceptible to morphine than normal, middle-aged, vigorous ones. A dog depressed by morphine should be handled gently and quietly because roughness and noise may awaken it and provoke delirium. The emetic actions of morphine may cause great inconvenience if it is not anticipated. Conversely, it is a definite advantage to have the stomach emptied in the event fasting was insufficient prior to anesthesia and surgery.

Premedication with sufficient morphine will decrease the total amount of general anesthetic required for surgical anesthesia to one-half or perhaps even to one-third. This supports the concept of balanced anesthesia and increases the safety of anesthetic procedures.

Oral administration could potentially be of value for the control of pain in dogs; however, the absorption, and therefore the efficacy, are variable. The use of oral sustained-release products does not prolong the duration of action in dogs (Dohoo and Tasker 1997).

Morphine is of value postoperatively for overcoming the recurring delirium observed in dogs recovering from anesthesia with pentobarbital. Without a depressant such as morphine, a dog may, by its struggles, induce hemorrhage, injury, or fracture or open a surgical incision.

Traditionally, morphine has been used cautiously in cesarean section of the dog because of fetal respiratory depression. It now appears that fetal respiratory movements are not abolished by doses of morphine that depress maternal respiration and produce maternal analgesia. However, they may be depressed by large doses of morphine. A large dose also interferes with uterine contraction and parturition.

By virtue of its morphine content as well as all the components in opium, *Paregoric*, USP, is used for its antidiarrheal effect. The oral dose recommended for the dog is 0.05–0.06 mL/kg administered every 8 or 12 hours (Chiapella 1980).

CATS. An effective SC analgesic dose of morphine in the cat is 0.1 mg/kg (Davis and Donnelly 1968). Other investigators have also found that SC administration of morphine (0.1 mg/kg) produces effective analgesia in the cat (Watts et al. 1973). Preanesthetic medication of cats with morphine (0.5 mg/kg) is probably valueless in ketamine anesthesia; morphine administered intramuscularly at this dose may induce respiratory depression (Hatch 1973).

For postoperative use, Heavner (1970) recommends morphine in the cat up to 0.1 mg/kg intravenously for management of pain. He noted that recovery from anesthesia is smoother, and upon awakening the animals lie quietly.

GUINEA PIGS, MICE, AND RATS. Morphine may be used subcutaneously or intramuscularly as a preanesthetic agent in the guinea pig and rat (Strobel and Wollman 1969) prior to parenteral or inhalant anesthetics; the recommended dose in these species is 2–5 mg/kg. According to Strobel and Wollman (1969), the usual analgesic and sedative doses of morphine exert an effect within 15 minutes of SC administration and last several hours. In the rat, mouse, and guinea pig, Wright et al. (1985) recommend a SC dose of 10 mg/kg morphine.

RABBITS. Morphine has a profound depressant effect in the rabbit. The IM use of morphine (8 mg/kg) is advocated 30 minutes prior to IV thiamylal (20 mg/kg) anesthesia. Atropine (0.2 mg/kg) is also administered intramuscularly at the same time as the morphine injection. A SC or IM dose of 5 mg/kg morphine is also recommended by Wright et al. (1985).

SWINE. Morphine has more CNS stimulant than depressant effects in the pig. However, it is used successfully for analgesic effect in the pig prior to chloralose and barbiturate anesthesia (Booth 1969); the recommended IM dose is 0.2–0.9 mg/kg. The mechanism of the excitatory effect produced by morphine in the pig is probably similar to that described in the cat.

SUBHUMAN PRIMATES. Comparatively large doses (1–3 mg/kg) of morphine are necessary for chemical restraint and sedation of the chimpanzee (Clifford 1971). The dosage for the dog is recommended for adequate sedation and safe management of the subhuman primate (Soma 1971). Wright et al. (1985) recommend 1–2 mg/kg morphine by the SC route in monkeys.

HORSES. Morphine and other opiates have been used in the horse for various ailments, but particularly to relieve acute pain of spasmodic colic. Morphine (0.22 mg/kg) is administered intramuscularly or slowly by the IV route (White 1981). For preanesthetic use, morphine is given in an IV dose of 0.12 mg/kg (Muir et al. 1978). Although some patients are relieved, many horses show undesirable and dangerous central stimulation and excitement. Loss of coordination occurs in the horse between 20 and 100 minutes after IV administration of 2.4 mg/kg morphine and lasts up to 7 hours (Combie et al. 1979). Horses walk, stagger, or bump into walls and appear to be unaware of their surroundings; they have the capability of making appropriate postural corrections in spite of coordination difficulties. Some clinicians contend that overdosing is the reason morphine has fallen into disrepute in treatment of spasmodic colic in the horse.

Morphine (0.1 mg/kg) can be detected in blood up to 48 hours and in urine for 144 hours after IV administration in the horse (Combie et al. 1983). A serum half-life for this dose is nearly 88 minutes.

Phaneuf et al. (1972) reported IV use of morphine chlorhydrate (1 mg/kg) in two ponies with classic forms of colic. The analgesic effect produced by the drug resulted in a hyperactive but uniform contraction of the jejunum. The jejunal spasms disappeared, motility of the colon became prominent, and the stomach remained quiescent.

Morphine has been used satisfactorily with xylazine for sedation and analgesia in the horse (Klavano 1975). Specific information on dosage and use is discussed under the section on xylazine in Chap. 14.

RUMINANTS. Morphine and other related derivatives have not been used in ruminants for clinical purposes. Experimentally, it is known that opioids inhibit cyclic forestomach motility in various ruminant species. Normal cyclic motility of the reticulorumen of sheep is inhibited by opioids that appear to act through central and peripheral mechanisms (Maas and Leek 1985). Central action leads to a reduced frequency and amplitude of the cyclic contractions. Both the central and peripheral inhibitory actions of the opioids upon the rumen can be antagonized by naloxone.

Codeine Phosphate. *Codeine Phosphate,* USP (methylmorphine), occurs in opium to the extent of around 0.5%. Most of it is produced semisynthetically from morphine. The phosphate salt is more widely used than codeine sulfate despite respective solubilities in water of 2.3 and 30 parts.

Codeine is metabolized rapidly by the tissues of humans, dogs, and rats. Metabolic alteration followed by rapid urinary excretion begins a few minutes after IM injection and after a slight delay following oral administration. About one-half an ordinary dose is eliminated within 6 hours and all within 24 hours. In the dog, about 50% of the dose is excreted in a conjugated (glucuronide) form in the urine. Limited conversion of codeine to morphine does not occur in the dog as in humans. Excretion products in humans include norcodeine, conjugated codeine, morphine, and traces of codeine in the feces. Interestingly, codeine is one-tenth as potent as morphine when administered to intact animals and only one-hundredth as potent in the isolated guinea pig ileum (Pert and Snyder 1973).

Codeine is widely used to depress the cough center. The dose of codeine should be increased proportionately over that of morphine to produce the desired depression of the cough reflex with less undesirable side action. Unfortunately, codeine possesses some of the constipating action of morphine; therefore, large doses or prolonged administration may result in constipation. Since the analgesic action of codeine is less than morphine, codeine is not commonly used in animals for control of severe pain. Addiction to codeine is uncommon.

Codeine is used in an expectorant and cough syrup mixture at 1.1–2.2 mg/kg to allay irritating coughs in dogs; this level is administered orally 3–4 times daily. For additional information on the cough-suppressant or antitussive action of codeine and related derivatives, see Chap. 54.

Analgesic dosages of codeine for laboratory animals are: rat, SC dose, 6.25–25 mg/kg; mouse, SC dose, 25.5 mg/kg; and rabbit, oral or IV dose, 10 mg/kg (Wright et al. 1985). Codeine can also be used as an orally administered analgesic in the dog. The dose is 0.5–2.0 mg/kg every 6–8 hours.

Hydromorphone Hydrochloride. *Hydromorphone Hydrochloride,* USP (Dilaudid), is about five times more potent as an analgesic than morphine. In the dog it produces less nausea, emesis, and GI disturbance than morphine. It is soluble in 3 parts of water. The SC dose for the dog is 1.1–2.2 mg/kg.

Oxymorphone Hydrochloride. *Oxymorphone Hydrochloride,* USP (Numorphan), is approximately 2.5 times as potent as hydromorphone and about 10 times more potent than morphine on an mg/mg basis. See Table 13.1 for its chemical relationships with morphine and other morphine substitutes.

This narcotic analgesic is potent when used alone or in combination with neuroleptic agents or barbiturates in the dog and cat. To avoid precipitation, oxymorphone must not be mixed with a barbiturate in the same syringe. Naloxone is an effective antagonist of oxymorphone. Oxymorphone is approved by the FDA for use in the dog and cat.

In the cat, a combination of oxymorphone (0.165 mg/kg) and triflupromazine (1.1 mg/kg) has proved satisfactory (Reid and Frank 1972). This neuroleptanalgesic mixture is followed with IV ketamine (1.1–2.2 mg/kg). According to Reid and Frank (1972), the combination of oxymorphone and triflupromazine can be administered by the SC, IM, or IV route. They recommend that ketamine not be administered until after oxymorphone and triflupromazine have taken effect because simultaneous administration of all three drugs induces prolonged apnea resembling the "locked chest" syndrome described in humans.

When used alone, preanesthetic effectiveness of oxymorphone is limited in the dog and cat because its CNS depressant effects are slight (Palminteri 1963). It produces a mild ataxia and hyperesthesia in the cat when used by itself. In combining the narcotic analgesic with a tranquilizer, such as acepromazine or valium, or with an α_2 agonist, such as xylazine, a greater degree of neurolepsia or tranquilization is achieved. Oxymorphone (1.5 mg/mL) is used in combination with triflupromazine (20 mg/mL) by mixing equal volumes of both drugs in the same syringe for IV, IM, or

TABLE 13.2—Parenteral doses of a mixture of equal volumes of oxymorphone (1.5 mg/ml) and triflupromazine (20 mg/ml) required to produce analgesia in small animals

Animal	Body weight	Volume of narcotic-tranquilizer mixture
	(kg)	*(ml)*
Dogs	0.9–2.3	1.0
	2.3–6.8	1.0–2.0
	6.8–13.6	2.0–4.0
	13.6–27.2	4.0–6.0
	27.2+	6.0–8.0
Cats	Small	0.5–1.0
	Large	1.0–2.0

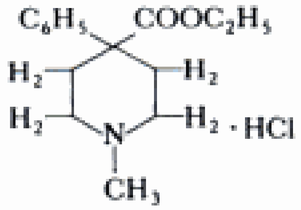
TABLE 13.3—Oxymorphone doses approved by the FDA for the dog and cat

Animal	Body weight	Dose
	(kg)	*(mg)*
Dogs	0.9–2.7	0.75
	2.7–6.8	0.75–1.5
	6.8–13.6	1.5–2.5
	13.6–27.2	2.5–4.0
	Over 27.2	4.0
Cats	Small	0.4–0.75
	Large	0.75–1.5



Meperidine Hydrochloride

FIG. 13.3

SC administration. For the dosage schedule recommended in the dog and cat, see Table 13.2.

In the dog, premedication with oxymorphone reduces the amount of thiamylal required to produce surgical anesthesia by one-third to two-thirds. Oxymorphone induces minimal cardiorespiratory changes in the dog. It produces mild respiratory depression with an increase in P_aCO_2 and decrease in tidal volume. Oxymorphone administration results in an increase in arterial blood pressure and stroke volume. Heart rate decreases along with slight decreases in cardiac output (Copeland et al. 1987; Haskins et al. 1991). Use of the analgesic agent prior to thiamylal requires IM or SC doses of oxymorphone varying from 0.065 to 0.44 mg/kg. The lower doses are administered to the large breeds. For all dogs, the average dose is 0.198 mg/kg. Thiamylal (2.5%) is administered intravenously to effect 45–90 minutes after administration of oxymorphone.

Oxymorphone doses approved by the FDA for IV, IM, or SC administration in the dog and cat are given in Table 13.3.

For postoperative pain, oxymorphone is recommended in an IV dose of 0.1 mg/kg every 4–6 hours for the cat and dog (Heidrich 1985). In the horse, it is recommended for postoperative pain in either an IV or IM dose of 0.2–0.3 μg/kg.

Although more work is needed to evaluate the safety and efficacy of oxymorphone, it has been used in equine colic intramuscularly or intravenously (10–15 mg/mature horse) (Hackett 1976). Oxymorphone (22 μg/kg) administered intramuscularly or slowly by the IV route has been recommended for alleviation of pain associated with equine colic (White 1981). For preanesthetic use, oxymorphone is recommended in an IV dose of 30 μg/kg (Muir et al. 1978).

Meperidine Hydrochloride. *Meperidine Hydrochloride*, USP (Demerol Pethidine, Dolantin) (Fig. 13.3), was synthesized in Germany during a search for an atropine-like drug having smooth muscle spasmolytic activity (Eisleb and Schaumann 1939). Meperidine is not only spasmolytic but also analgesic and sedative. The hydrochloride salt is used in medicine. It is a colorless crystalline powder with a neutral reaction, a slightly bitter taste, and ready solubility in water. The aqueous solution is not decomposed by a short period of boiling.

Meperidine and its related derivative *Diphenoxylate Hydrochloride*, USP, are Schedule II drugs subject to the Controlled Substances Act of 1970. Diphenoxylate, an antiperistaltic agent, in combination with atropine is classified as a Schedule V preparation.

ADMINISTRATION. Meperidine is best administered intramuscularly in animals. The absorption after IM administration can be somewhat variable (Waterman and Kalthum 1989, 1990). The SC route is not preferred because local irritation and pain may be produced. Oral administration is not advised in large animals because of the cost. If the drug contacts buccal mucosa, particularly in the cat, considerable irritation and salivation result. IV injection must be made slowly to avoid cardiovascular collapse. Following IM or SC administration in the cat, emesis does not occur, but defecation occurs in some animals.

METABOLISM AND FATE. Meperidine is absorbed rapidly following SC, IM, or oral administration. The drug is largely inactivated in the liver. This results in a low bioavailability of meperidine due to a first-pass effect after oral administration (Ritschel et al. 1987). A small amount is excreted unchanged in urine; the major part of a given dose is demethylated (normeperidine) and hydrolyzed before being excreted. Parahydroxymeperidine has also been identified in the rat. Both normeperidine and parahydroxymeperidine have been shown to possess less analgesic activity than meperidine (Dahlstrom et al. 1979). The metabolite normeperidine is more toxic and possesses greater convulsant activity than meperidine, the parent compound.

There is considerable species variation with respect to metabolism of meperidine (Caldwell et al. 1979). Biotransformation of meperidine in the rat is considerably different from that in humans and monkeys. Of the monkeys, the mangabey (*Cerecebus tarquinus*) provides a good metabolic model for humans, whereas the mona (*Cercopithecus mona*) and patas (*Erythrocebus patas*) monkeys are less acceptable in metabolism studies of meperidine.

In humans, only about 5% of meperidine administered is excreted unchanged; the remaining portion undergoes *N*-demethylation to normeperidine acid or conjugation with glucuronic acid. About 60% of meperidine administered in humans can be recovered (Greene 1968); 5% of the drug is unchanged, 5% is in the form of unbound normeperidine, 20% is meperidine acid, 7% is normeperidine acid, and 12% each is recovered as bound meperidine and normeperidine. Disposition of the remaining 40% of the parent compound is unknown. Biotransformation of meperidine in humans occurs at the rate of 10–20%/hour; *N*-demethylation occurs through hepatic microsomal enzyme activity together with nicotinamide adenine dinucleotide phosphate and oxygen. Only the unchanged meperidine molecule can be metabolized by the liver; all other metabolic changes or degradation occur to some degree in extrahepatic tissues.

When meperidine (22 mg/kg) is administered intravenously, Davis and Donnelly (1968) found the plasma half-life to be 0.7 hour in the cat. Despite the short half-life in plasma, the analgesic effect of 11 mg/kg of the drug given intramuscularly is apparent at 2 hours but not at 0.5 or 4 hours after administration. In the dog, the half-life of intravenously administered meperidine is 0.75 hours, the volume of distribution is 2.4 L/kg, and the total clearance is 42.5 mL/min/kg (Ritschel et al. 1987). Because duration of effective plasma levels of meperidine is short and the biotransformation is rapid, Davis and Donnelly (1968) stated that meperidine probably will serve better as a preanesthetic drug than in management of severe pain in cats.

Meperidine is rapidly cleared from pony plasma after IV administration (Alexander and Collett 1974). The estimated half-life of the drug is 66 ± 8.7 minutes. Alexander and Collett found that less than 5% of the administered dose (350 mg IV) is excreted unaltered in pony urine during the 48 hours after administration.

Pharmacokinetic studies in the pregnant ewe indicate that fetal blood levels of meperidine peak less than 10 minutes after an IV injection (Mirkin 1975). Serum concentrations in the fetus are generally greater than those in corresponding samples from maternal subjects. A single IV injection of meperidine (0.85–2.5 mg/kg) into the pregnant ewe is not associated with significant effects on maternal or fetal arterial blood pressure and heart rate (Jenkins and Dilts 1971).

THERMOREGULATORY EFFECT. In the cat, following SC injection of large doses (30–50 mg/kg) of meperidine, a marked rise to 40.5–41.6° C occurs in rectal temperature. This appears to be a dose-related phenomenon. Inasmuch as morphine induces a hyperthermic response in the cat, the mechanism of meperidine-induced hyperthermia may be similar to that of morphine.

CARDIOPULMONARY EFFECT. Following an IM dose of 10 mg/kg meperidine, reduction in heart rate and drop in the systemic arterial pressure occur in dogs. Generally, the fall in blood pressure is moderate, and occurs 10–20 minutes after IM injection, with return to the control level in 30 minutes. The decline in systemic arterial pressure is probably the result of peripheral vasodilation following release of histamine.

A significant degree of bronchoconstriction occurs in the dog following an IV dose of 0.5 mg/kg (Shemano and Wendel 1965). Also, meperidine administered at 2.5 mg/kg intravenously produces a 22% decrease in lung capacity. Shemano and Wendel suggested that the bronchoconstrictor effect of meperidine and morphine may be due to a combination of central vagal stimulation and histamine release.

ANALGESIC ACTION. The analgesic effect of meperidine is intermediate between codeine and morphine. In dogs, meperidine (4.4 mg/kg) administered intramuscularly every 3–6 hours has been used to depress the cough reflex and in treatment of cardial "asthma." In the horse, meperidine produces analgesia within a few minutes following IV administration and 15–25 minutes after an IM injection.

SPASMOLYTIC ACTION. The spasmolytic activity of meperidine is significant but considerably less than morphine and methadone. Meperidine will relax the intestine, bronchi, ureter, and, to some degree, uterus. Meperidine, morphine, and methadone depress intestinal peristalsis in the dog. This effect is capitalized upon in the use of paregoric, a compound containing morphine, or diphenoxylate hydrochloride, a meperidine derivative for antidiarrheal purposes.

The ratio of doses producing the same degree of intestinal inhibition is morphine 1 and meperidine 750. Because the ratio of doses producing a given analgesic effect is 1:10, meperidine has an advantage of 75 to 1 over morphine when an analgesic drug is needed that does not depress intestinal motility. It is apparent that meperidine possesses a marked advantage over morphine for relief of postoperative pain because it can be given in many times (up to 750) the dose of morphine before it depresses intestinal propulsion as much.

Diphenoxylate hydrochloride is combined with atropine as adjunctive therapy in management or control of severe diarrhea in humans. Control of diarrhea occurs by virtue of the antiperistaltic actions of both diphenoxylate and atropine.

TABLE 13.4—Effect of varying doses of meperidine in the cat

Dose	Number tested	Number showing excitation	Number showing muscular spasms	Number showing convulsions	Deaths

50	10	10	10	9§	0

Source: Booth and Rankin 1954.
Note: Pentobarbital (15–20 mg/kg) was used as an anticonvulsant in 3 cats,* 1 cat,† and 7 cats§ of these respective groups.

The diphenoxylate-atropine mixture (Lomotil) has been used in the UK for treatment of feline diarrhea. Not more than 0.5 mg/kg based upon the diphenoxylate content of the mixture is suggested by the oral route of administration (Ormerod et al. 1978). The mixture, in tablet form, contains diphenoxylate (2.5 mg) and atropine (0.025 mg). Toxicity induced by the drug preparation in cats results in extreme excitement, restlessness, and marked mydriasis with visual impairment. A goose-stepping gait, loss of balance, extension of claws, and leaping everywhere are additional signs seen following overdosages of the mixture. In the dog, an oral dose of diphenoxylate (2.5–5 mg total dose) is used every 6 or 8 hours for antidiarrheal purposes (Chiapella 1980).

Caution in the use of diphenoxylate with CNS depressant agents must be considered. It may potentiate the actions of barbiturates, tranquilizers, and other CNS depressants.

Naloxone reverses the action of diphenoxylate. In the USA, diphenoxylate-atropine has not been approved for use in animals by the FDA.

TOXICITY. SC doses in excess of 20–30 mg/kg can produce excitement and clonic convulsions in cats (see Table 13.4). Convulsions can be controlled by injection of pentobarbital. Barbiturates can be used successfully to antagonize lethal convulsive effects of meperidine. However, meperidine potentiates the depressant effect of the barbiturates upon respiration and will only increase the certainty of death if administered in barbiturate intoxication. Naloxone is an antagonist of the respiratory depressant and toxic effects of meperidine. However, naloxone does not antagonize CNS convulsions and other signs of CNS stimulation such as hyperreflexia and tremors (Dystra and Leander 1978).

Normeperidine is considered to be more toxic than the parent drug meperidine. Its accumulation may result in toxicologic consequences. However, prolonged administration of meperidine to dogs in amounts up to six times the recommended therapeutic dose produces no toxic effects other than slight anorexia and loss of weight. Although no addiction to meperidine has been demonstrated in animals, addiction manifested by withdrawal symptoms occurs in humans.

CLINICAL USE. In dogs and cats, meperidine given preanesthetically reduces the period of excitement and reduces the amount of anesthetic needed. There is individual variation in the depressant effects of meperidine.

DOGS AND CATS. In the dog, meperidine is used intramuscularly for preanesthetic medication varying from 2.5 to 6.5 mg/kg (Soma 1971). The postanalgesic dose recommended in the dog is 5–10 mg/kg intramuscularly. Duration of analgesia induced by meperidine is approximately 45 minutes. In contrast to morphine, meperidine does not produce miosis in the dog; parenteral administration (4 mg/kg) causes mydriasis (Martin 1984).

In the cat, the IM dose of meperidine is 2.2–4.4 mg/kg for preanesthetic medication (Chase 1977). Premedication of cats with meperidine is probably of no value in ketamine anesthesia; IM meperidine (5 mg/kg) may induce respiratory depression (Hatch 1973).

SWINE. Meperidine (10 mg/kg) administered subcutaneously in large sows and boars contributes little toward restraint. For preanesthetic medication in the pig, meperidine (1–2 mg/kg), promazine hydrochloride (2 mg/kg), and atropine (0.07–0.09 mg/kg) work satisfactorily prior to barbiturate and inhalant anesthesia (Booth 1969). All these preanesthetic preparations are administered intramuscularly in separate sites 45–60 minutes prior to induction of anesthesia.

HORSES AND CATTLE. Total IV and IM doses of meperidine recommended for the adult horse are 500 and 1000 mg respectively. It must be given slowly intravenously because dangerous arterial hypotension can occur.

In cattle an IM dose of 500 mg is recommended. Meperidine is used in the mare to relieve pain and discomfort following cesarean section (Cohen 1975). It has also been used to treat equine colic, especially acute spasmodic conditions. However, meperidine (2.2 mg/kg) administered intramuscularly produces only an

TABLE 13.5—Doses and indications of meperidine for use in laboratory animals

Species	Dose	Route of administration	Major indications	Reference
	(mg/kg)

Rate	20	SC,IM	Analgesia	Wright et al. 1985
Hamster	2	IM	Preanesthetic	—
Guinea pig	2	IM	Preanesthetic	Maykut 1958
Rabbit	10	SC,IM	Analgesia	Gardner 1964
Subhuman primates	2–4	IM	Analgesia	Wright et al. 1985

inconsistent and transient analgesia in the horse following experimentally induced colic; xylazine is a superior analgesic compared to meperidine, pentazocine, and dipyrone for treatment of induced colic (Lowe 1978). A dose of meperidine as high as 4 mg/kg administered intramuscularly or subcutaneously is recommended for control of pain in horses (Baggot and Cooper 1980).

Spontaneous locomotor activity is prominent in the horse after an IV dose of 5 mg/kg meperidine (Combie et al. 1979). For the first 14 minutes postinjection, meperidine induces incoordination, trembling, and immobility. However, the locomotor effect is relatively brief; it peaks at about 30 minutes and returns to normal by about 3 hours (Combie et al. 1979). An IV dose of 2.5 mg/kg elicits a modest increase in motor activity, whereas 1 mg/kg has no effect.

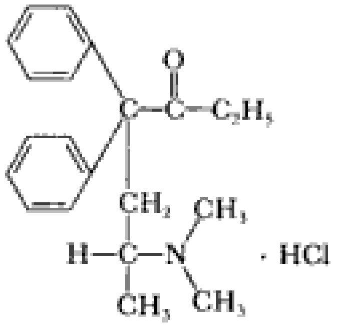
In cattle, the drug is used for calving to calm the nervous heifer and provide analgesia during parturition. Meperidine does not inhibit uterine contractions in cattle.

LABORATORY ANIMALS. Meperidine is useful as an analgesic in laboratory species. Doses are given in Table 13.5.

On a body weight basis, the rhesus monkey is twice as sensitive to meperidine as the squirrel monkey. According to Robinson and Janssen (1980), 10 mg/kg meperidine administered subcutaneously for postsurgical analgesia in a colobus monkey (*Colobus guereza kikuyensis*) is followed within several minutes by respiratory arrest. Administration of oxygen and an IV dose (0.04 mg/kg) of naloxone are effective resuscitative measures in reversal of respiratory arrest resulting from meperidine overdosage.

EXOTIC ANIMALS. Meperidine (2.2–4.4 mg/kg) has been used subcutaneously in bears and large cats for analgesia (Wright et al. 1985). For immobilization purposes in the elephant, an IM dose of 0.03 mg/kg is recommended (Tamas and Geiser 1983).

Methadone Hydrochloride. Two proprietary names for *Methadone Hydrochloride*, USP, are Amidone and Dolophine. Methadone was synthesized in Germany in 1941 as a result of the continuing search for a substitute for morphine (Fig. 13.4). In 1973, methadone was removed from general medical use. It has been reinstated as a Schedule II drug and is again available for veterinary medical use. Methadone is a bitter, white, crystalline compound that is readily soluble in water. The *l*-isomer has 25 times the analgesic potency of the *d*-isomer. This drug is discussed in greater detail in the 7th edition of this text.



Methadone Hydrochloride

FIG. 13.4

CLINICAL USE. In the horse, methadone (0.11 mg/kg) and acepromazine (0.11 mg/kg) have been administered in combination by the IV route to provide analgesia and restraint for treatment of wounds, loading unruly animals into transporting vehicles, suturing of wounds, and various types of minor surgery (Schauffler 1969). CNS depression occurs within 30 seconds following injection; within 3 minutes, the effect is usually sufficient to carry out various treatments or surgical procedures. However, peak CNS depression may not be attained for 15 minutes following administration of methadone-acepromazine; duration of the effect is about 1 hour. Recovery occurs gradually over a 6- to 12-hour period. Occasionally, a horse may be slightly drowsy for up to 3 days after receiving this drug combination (Schauffler 1969).

Horses ordinarily do not become recumbent following methadone-acepromazine even at high dosages. The animals may appear somnolent but will usually retain their standing position (Schauffler 1969). Moreover, horses are sufficiently free of incoordination so there is little hazard of their falling upon, stepping upon, or otherwise injuring attending personnel. If the animals become recumbent, they can be returned to the standing position without difficulty.

Methadone (0.04 mg/kg) plus acepromazine (0.04 mg/kg) has been used intravenously in the horse prior to IV ketamine (2–2.5 mg/kg) (Parsons and Walmsley 1982). The mean time between administration of the premedication and ketamine was 15 minutes; time of standing from induction averaged 13 minutes. More data are needed to determine the safety and efficacy of using these drugs in combination.

Fentanyl Citrate. *Fentanyl Citrate,* USP (Sublimaze), is a phenylperadine derivative. It is more lipid soluble than morphine, which contributes to its rapid onset and short duration of action (Hug and Murphy 1981). Its analgesic properties are at least 100 times that of morphine. It is a full opioid agonist and is active at μ, κ, and δ receptors. It has a high abuse potential and is a Schedule II drug.

METABOLISM AND FATE. Fentanyl is metabolized by the liver by hydroxylation and dealkylation. The primary route of excretion for the metabolites is in the urine (McLain and Hug 1980). It is highly protein bound and undergoes significant tissue redistribution, which leads to some variability in the rate of excretion of the drug. It has a steady-state Vd of 3–5 L/kg, a clearance rate of 10–20 mL/min/kg, and an elimination half-life of 2–4 hours (Bailey and Stanley 1994).

CARDIOPULMONARY EFFECTS. In the dog, fentanyl given alone induces analgesic, respiratory, and cardiovascular effects within the same range of plasma concentrations. It does not produce respiratory arrest when injected intravenously at 2.5, 5, 20, 40, and 100 μg/kg at 5-minute intervals to a cumulative dose of 167.5 μg/kg given over 20 minutes. After these doses, spontaneous respiration is maintained in all animals; respiratory rate, P_aO_2, heart rate, and cardiac output are reduced to about one-half at the peak effect of fentanyl. Doses in excess of those required to produce complete analgesia do not interfere with adequacy of oxygenation (Arndt et al. 1984). Even doses up to 3 mg/kg failed to produce apnea or severe hypercapnia in spontaneously breathing dogs (Bailey et al. 1987). Fentanyl appears to have minimal direct cardiac depressant effect (other than bradycardia), although some negative inotropic effect is seen at excessive doses (Montomura et al. 1984). There is an overall sympatholytic effect seen with fentanyl administration (Tayeyama et al. 1993). The respiratory effect of fentanyl is similar to that of morphine in that it depresses the patient's response to increases in arterial carbon dioxide partial pressure. Its respiratory depressant effects are often of surprisingly long duration and may exhibit a biphasic pattern. This is probably due to the significant amount of fentanyl sequestered in peripheral tissues, which must then reenter the plasma before elimination (Bailey and Stanley 1994).

CLINICAL USE. In veterinary medicine fentanyl was most commonly used with droperidol (see Chap. 14) in the fixed drug combination Innovar-Vet, which is no longer available. Each milliliter contained 20 mg droperidol and 0.4 mg fentanyl.

Fentanyl (without droperidol) is used prior to general anesthesia or as part of a balanced anesthesia protocol, also termed neuroleptanalgesia (Sawyer 1985). In dogs it is often used with other tranquilizers such as medetomidine (20 or 40 μg/kg) IM and fentanyl (2 μg/kg) IV (England and Clarke 1989) or xylazine (0.2 mg/kg) IV, glycopyrrolate (0.01 mg/kg) IV, and fentanyl (10 μg/kg) IV. Fentanyl (55 μg/kg) and xylazine (1.1 mg/kg) have been used in the horse (Pippi and Lumb 1979).

Fentanyl is also available in a transdermal delivery system (Duragesic). The delivery system consists of a small reservoir with a semipermeable membrane that is applied to the skin over a hairless area. The reservoirs come in several sizes to adjust the dosage rate and are labeled to indicate the total administration rate in micrograms per hour. The sizes available are 25, 50, 75, and 100 μgrams/hr. The dose most commonly used in dogs and cats is 2–4 μg/kg/hr. In dogs the absorption rate is variable and it can take up to 24 hours for the plasma concentration to reach a steady state but the plasma concentrations obtained are highly variable (Kyles et al. 1996; Egger et al. 1998). The lipophilic nature of fentanyl allows successful transdermal administration since the rate-limiting step is diffusion through the lipophilic stratum corneum (Guy et al. 1987; Samir and Flynn 1989).

Sufentanil Citrate. *Sufentanil Citrate,* USP (Sufenta) is a phenylperadine derivative similar to fentanyl. It is 5–10 times more potent than fentanyl but has a safety margin over 6 times larger than fentanyl (Stoelting 1991). Sufentanil is more lipid soluble than fentanyl. It is a full opioid agonist and is a Schedule II drug because of its high abuse potential.

METABOLISM AND FATE. Sufentanil is metabolized by the liver primarily by dealkylation and demethylation. Most of the metabolites are excreted in the urine (60%) in dogs and in the feces (62%) in rats (Meuldermans et al. 1987). In plasma, sufentanil is highly protein bound. It has a steady-state Vd of 2.5–3.0 L/kg, a clearance rate of 10–15 mL/min/kg, and an elimination half-life of 2–3 hours (Bailey and Stanley 1994).

CARDIOPULMONARY EFFECTS. Equipotent doses of fentanyl and sufentanil produce similar cardiovascular and respiratory effects.

CLINICAL USE. Sufentanil is generally used when it is desirable to have an anesthetic protocol with excellent cardiovascular stability. It is administered as a continuous infusion with concurrent use of a tranquilizer or inhalation anesthetic. When a sufentanil infusion was administered in conjunction with lenperone, the sufentanil-induced cardiovascular changes were minimal (Benson et al. 1987).

Alfentanil Hydrochloride. *Alfentanil Hydrochloride,* USP (Alfenta), is a phenylperadine derivative similar to fentanyl. It is less potent than fentanyl and has a shorter half-life. The short duration of action makes it very appropriate for use as an infusion. It is more lipid soluble and exhibits greater protein binding than fentanyl (Stoelting 1991). It is a full opioid agonist and is a Schedule II drug because of its high abuse potential.

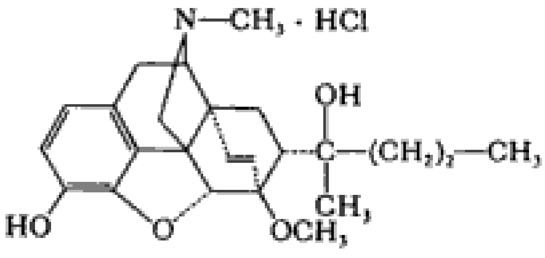
METABOLISM AND FATE. Alfentanil is metabolized by the liver primarily by dealkylation and demethylation. Most of the metabolites are excreted in the urine (75%) in both dogs and rats (Meuldermans et al. 1987). In plasma alfentanil is highly protein bound. It has a steady-state Vd of 0.4–1.0 L/kg, a clearance rate of 4–9 mL/min/kg, and an elimination half-life of 1–2 hours (Bailey and Stanley 1994). Its short duration of action is a result of redistribution from the brain to other tissues, and its rapid metabolism results in minimal accumulation.

CLINICAL USE. In dogs infusions of 8 μg/kg/min produced a 69% reduction in the minimum alveolar concentration (MAC) of enflurane (Hall et al. 1987). In humans, alfentanil can be used for induction of anesthesia (150–300 μg/kg IV) followed by an infusion of 25–150 μg/kg/hr with an inhalation anesthetic (Ausems et al. 1983). In the horse, doses of 20 and 40 μg/kg resulted in increased motor activity for a short period of time (Pascoe et al. 1989).

Carfentanil Citrate. *Carfentanil Citrate,* USP (Wildnil) is another phenylperadine derivative that is an extremely potent opioid agonist. It is approximately 10,000 times more potent than morphine (Mather 1983). It is currently labeled only for the immobilization of cervidae but it has been used on numerous other species. It is a Schedule II drug and requires special registration with the US Drug Enforcement Agency before it can be purchased. The normal dose used for capture is 0.005–0.02 mg/kg injected intramuscularly. Nielson (1996) has numerous doses for carfentanil as well as other capture drugs. Carfentanil can be dangerous to the user, and the manufacturer recommends the user takes every precaution to avoid human exposure. In addition, the user should never work alone, and an appropriate opioid agonist (such as diprenorphine) should be immediately available.

Remifentanil Citrate. *Remifentanil Citrate,* USP is the newest synthetic opioid. It is 20–30 times more potent than alfentanil. Remifentanil has the distinction of having a very large therapeutic index (33,000) and an extremely short half-life (7.5 min) (Stanley 1994). This drug is the first in a group of new opioids potentially able to safely function as anesthetic agents when used alone.

Etorphine Hydrochloride. *Etorphine Hydrochloride,* INN (M-99, Oripavine), is a semisynthetic opiate derivative having up to 10,000 times the analgesic potency of morphine (Harthoorn 1965a). Chemically, it is 6,14-endoetheno-7α-(2-hydroxy-2-pentyl)-tetrahydro-oripavine hydrochloride (Fig. 13.5). Etorphine binds to the opioid receptors in a number of regions within the CNS (see discussion on opioid receptors in this chapter).



Etorphine Hydrochloride

FIG. 13.5

Etorphine is commonly used as a capture drug and it is generally recommended to dose heavily and then reverse as soon as possible with diprenorphine, the antagonists of etorphine. Insufficient dosage or underdosing with etorphine may result in hyperexcitability and other complications. It should never be used unless diprenorphine or other suitable antagonists are available.

FREE-RANGING WILD ANIMALS. Etorphine was used in the early 1960s for field investigations in the immobilization and capture of exotic species (Harthoorn 1965b); since then it has been used extensively in the field of animal conservation (Harthoorn 1972).

The potency of etorphine is extremely impressive. One milligram is capable of immobilizing a rhinoceros weighing approximately 2000 kg; this is equivalent to 0.5 μg/kg. A dose of 4 mg is capable of immobilizing an African elephant weighing about 5000 kg; this amounts to less than 1 μg/kg (Harthoorn and Bligh 1965).

The action of etorphine can be antagonized or reversed by diprenorphine. If the action is not antagonized, the immobilized state usually persists from 30 to 60 minutes. Used by itself in exotic species, the IM doses of etorphine that usually result in rapid immobilization, sedation, and analgesia are as follows (Alford et al. 1974):

Family	*Dose (mg/45 kg)*
Equidae (Mongolian horse, zebra)	0.44
Ursidae (black, grizzly, polar bear)	0.5
Cervidae (fallow deer, moose)	0.98
Bovidae (antelope, bighorn sheep)	0.09

According to Harthoorn (1966), the dose of etorphine for most exotic animals is about 1–2 mg (total dose); e.g., the zebra requires about 1.5 mg and the rhinoceros 1–1.5 mg (total dose). The IM dose of etorphine alone for chimpanzees is 0.66–1.76 μg/kg; for small primates it is 0.44–1.3 μg/kg (Wallach 1969).

Use of etorphine alone in the Asiatic working elephant at doses of 5–8 mg have also proved satisfactory for immobilization (Jainudeen et al. 1971). Etorphine has been successfully used for anesthesia in the two-stage castration of a 9-year-old Asian elephant; anesthesia was induced by an IM injection of 6 mg (Fowler and Hart 1973) and maintained by intermittent injections of 1 mg into an ear vein.

Etorphine has been used to immobilize the American alligator, red-ear turtle, and Galapagos tortoise (Wallach and Hoessle 1970). Immobilization of these poikilothermic animals was satisfactory. However, the total dose required to attain a desired affect is much greater on a body weight basis than those required in homeothermic species.

CAPTIVE WILD ANIMALS. Etorphine is used to immobilize many species of animals that are maintained in zoological establishments and circuses. It is used for diagnostic procedures and/or treatment in animals that are difficult and dangerous to approach.

In the camel (dromedary), etorphine (0.25–0.5 mg/45 kg) is administered by the IM route; IV administration is contraindicated (Higgins and Kock 1984). A maximum of 4 mg is suggested for the adult dromedary weighing 400–500 kg; for juvenile animals, a total IM dose of 0.5–2 mg is suggested.

Gatesman and Wiesner (1982) have found that the average effective IM dose for etorphine plus zylazine in bears is: polar bears, 7.312 μg/kg, with a maximum of 7.95 μg/kg; brown bears, 16.82 μg/kg. The IM dose of xylazine for bears is added to the etorphine; 10 mg xylazine is given to animals weighing 300 kg or more and 5 mg is used in animals weighing less than 300 kg. Hyaluronidase (150 IU) is also added to this mixture to increase the absorption rate. A blowpipe and dart system of 2 mL volume is used for delivering the drug mixture into the neck or shoulder musculature where body fat is thinnest. Other anatomic regions of the body may have up to 7.5 cm of subcutaneous fat; absorption of drugs is delayed and induction effects are much slower when the injection is made in body fat. For reversal of the effects of etorphine, IM and SC doses of diprenorphine are given. The lingual vein is also accessible in bears for administering the antagonist drug (Gatesman and Wiesner 1982).

Etorphine-xylazine has been used in a female greater kudu (*Tragelaphus strepsiceros*) for 14 immobilizations over a period of 9 months with satisfactory results (Kollias et al. 1983). Etorphine (7 μg/kg) and xylazine (130 μg/kg) are administered intramuscularly in the quadriceps femoris via projectile syringe. IV diprenorphine (14 μg/kg) reverses the effects of etorphine (after immobilization periods of 20–150 minutes) within a mean period of 2 minutes.

DOMESTIC SPECIES. Etorphine has been approved by the FDA in the USA for use only in wild or exotic species. Information is incomplete on tissue residue patterns as well as excretion of etorphine and its metabolites in food-producing animals. The use of etorphine in domestic species is discussed in greater detail in the 7th edition of this text.

PRECAUTIONS AND CONTRAINDICATIONS. Safe use of etorphine requires special precautions. Domestic animals should be properly controlled and restrained prior to IV or IM administration to avoid accidental self-injection. The lethal dose of etorphine for adult humans is small. It is estimated to be 30–120 μg (micrograms not milligrams!) (Haigh and Haigh 1980).

Accidental injections of small amounts of etorphine-acepromazine have led to serious respiratory depression and coma of a veterinary assistant (Firm 1973) and to death of a veterinarian (Vet Rec News and Reports 1976). Consequently, the manufacturer's license for production of the drug combination was temporarily suspended. The product was soon reinstated for use in animals following revised warnings by the manufacturer. In the event of an accidental injection of etorphine-acepromazine, warnings include immediate IV or IM administration of naloxone (0.8 mg); naloxone is to be repeated at 5-minute intervals if symptoms are not reversed. Reliance on the use of naloxone is emphasized by Ross (1986) rather than use of diprenorphine for antagonizing the effects of etorphine from accidental self-injection. If naloxone is unavailable, nalorphine hydrochloride should be administered intravenously or intramuscularly in a dose of 10 mg. Nalorphine can be repeated at 5-minute intervals if necessary up to a total of 4 mg. Adequate cardiopulmonary activity and/or resuscitation must be maintained until emergency medical assistance arrives.

Etorphine and its antagonist diprenorphine must not be used in domestic or wild animals intended for human consumption.

Propoxyphene Hydrochloride. The analgesic potency of *Propoxyphene Hydrochloride*, USP (Darvon), is less than that of codeine. Propoxyphene has weak analgesic potency and only 1/200 the affinity of morphine for receptor binding (Pert and Snyder 1973). It is structurally similar to the methadone molecule.

Because of hazards and potential toxicity of the drug, the FDA has considered the possibility of sharply curtailing or banning propoxyphene for human use (Smith 1979). A shift from Schedule IV to Schedule II has also been under consideration by the FDA and US Drug Enforcement Agency.

Propoxyphene has not been used to any great extent in clinical veterinary medicine. A dose of 2.2 mg/kg administered intramuscularly was found useful in obtunding experimentally induced pain (Davis and Donnelly 1968). Toxicity of propoxyphene has been studied in dogs and rabbits. Metabolization of the drug is rapid. Its major metabolite, norpropoxyphene, has a longer plasma half-life in the dog than propoxyphene (Page et al. 1979).

When dogs receive a single oral dose (40 mg/kg) of propoxyphene, signs of CNS toxicity develop (Page et al. 1979). Tremors, salivation, vomiting, and ataxia may occur. Convulsions develop following doses of 60 mg/kg and lethal effects are induced by 125 mg/kg.

Propoxyphene has been evaluated in three IV doses (0.5, 1, and 2.2 mg/kg) in the horse (Muir et al. 1980). Cardiopulmonary function is not altered by 0.5 or 1 mg/kg of the drug. Muscle fasciculation occurs in some animals following a dose of 0.5 mg/kg. A brief period of ataxia and muscle fasciculations develops after a dose of 1 mg/kg; increased motor activity also is seen and lasts about 30 minutes. The dose of 2.2 mg/kg is followed by increase in heart rate and arterial blood pressure; ataxia and disorientation also occur for a brief period and increase in locomotor activity that lasts several hours is observed. Naloxone (0.005 mg/kg) administered intravenously lessens increased locomotor activity or results in return of animals to a normal quiet behavior pattern.

In the rabbit, propoxyphene and norpropoxyphene produce cardiac arrhythmias and a number of electrocardiographic alterations (Lund-Jacobsen 1978).

Circulatory shock is induced in the pig by the IV infusion of 675–2025 mg propoxyphene administered at the rate of 15 mg/kg/min; a plasma concentration is attained between 9.6 and 15.3 µg/mL, which is a similar plasma concentration range considered to be lethal in humans (Sørenson et al. 1985).

Behavioral alterations in offspring of rats exposed to propoxyphene are known to occur (Vorhees et al. 1979). The drug appears to meet the criteria for being a pure behavioral teratogen.

Therapeutic efficacy of propoxyphene has not been determined in most species. Moreover, it has not been approved by the FDA for use in animals.

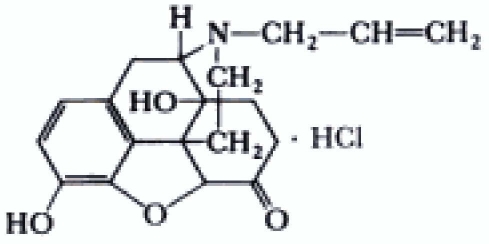
OPIOID ANTAGONISTS. Pure opioid antagonists of current importance in veterinary medicine include naloxone and diprenorphine.

Naloxone Hydrochloride. *Naloxone Hydrochloride,* USP (*N*–allylnoroxymorphone hydrochloride, Narcan), is approved by the FDA for use in the dog. Chemically, naloxone is 17-allyl-4,5α-epoxy-3,14-dihydroxymorphinan-6-one hydrochloride (Fig. 13.6).

Naloxone has a potency 10–30 times that of nalorphine. Unlike nalorphine, it lacks the agonistic effect that is highly desirable if the drug is to be depended on as an antagonist of narcotic analgesics. In general, naloxone is regarded as a virtually pure competitive antagonist. Consequently, it does not produce respiratory depression, which commonly occurs with other narcotic antagonists.

Naloxone is not subject to the Controlled Substances Act of 1970. This is an advantage over use of other narcotic antagonists that are subject to regulation under the act.

PHARMACOLOGIC ACTION. In low doses, naloxone has a high binding affinity for µ opioid receptors; both μ_1 and μ_2 receptors are blocked. Compared to µ receptors, large doses of naloxone are required to block δ opioid receptor activity. Moreover, κ opioid receptors, which have high binding affinity for ketocyclazocines, have a very low binding affinity for naloxone; extremely large doses of naloxone (20–30 times needed to block µ receptors) are necessary for blockade of κ receptors. The σ opioid receptor is insensitive to naloxone. Some of the functions of opioid receptors have been discussed previously in this chapter.



Naloxone Hydrochloride

FIG. 13.6

Although naloxone is considered to be a specific opiate antagonist, it also antagonizes the effects of nonopiate depressants, affects dopaminergic mechanisms, and antagonizes GABA. High doses of naloxone can initiate both biochemical and physiological effects (seizures or convulsions), mimicking those produced by GABA antagonists (Yaksh and Howe 1982). The prevalent idea that naloxone only induces an effect on specific opioid receptors needs revision. It is axiomatic that one should never accept the idea that a potent drug has but one action.

CARDIOVASCULAR SYSTEM. Naloxone has no effect upon arterial blood pressure in normotensive subjects (Zaloga et al. 1984). It acts upon sites (probably δ opioid receptors) within the CNS and/or at peripheral sites to improve cardiovascular function in experimental shock (Holaday and Faden 1980). Also, the protective action of naloxone depends on an intact pituitary-adrenal, medullary-sympathetic nervous system (Davis et al. 1984). The cardiovascular effects of naloxone in spinal shock are mediated by the parasympathetic nervous system and by release of dopamine. Additionally, other catecholamines (epinephrine and norepinephrine) are released by high doses of naloxone when administered after opioids. Apparently, opioid peptides modulate the release of catecholamines from the sympathetic nervous system by inhibiting their output (Mannelli et al. 1983).

Since naloxone also blocks the endogenous opiate ligand, β endorphin, it has been used experimentally in the dog for reversal of hypovolemic shock (Vargish et al. 1980). Beta endorphin, which is released during or following hemorrhagic shock, is blocked by naloxone from interacting with opioid receptors present in brain, heart, GI tract, kidney, adrenal glands, and possibly other tissues. An IV bolus of naloxone (2 mg/kg) and an infusion at 2 mg/kg/hr promptly increases systemic arterial pressure, left ventricular contractility, and cardiac output. This dose results in 100% survival, whereas untreated or control dogs die within 30 minutes. In canine endotoxic shock, naloxone also improves survival and cardiac performance; this indicates that endorphins or opioid receptors are involved in cardiovascular pathophysiology of endotoxic shock (Reynolds et al. 1980).

Since the studies of Vargish et al. (1980) and Reynolds et al. (1980) on shock, it has been established unequivocally that β-endorphin and ACTH concentrations in blood increase simultaneously in response to stress. Beta endorphin release has a potent arterial hypotensive effect that can be blocked by naloxone. It is also possible that naloxone may exert some of its protective effects in shock unrelated to its action as an opiate antagonist.

Administration of naloxone in the dog clearly indicates that it increases myocardial contractile force in a dose-dependent manner (Caffrey et al. 1985). Conversely, opiate peptides (endorphins) of circulating or myocardial origin appear to depress or decrease myocardial contractile force. The fact that naloxone releases catecholamines, thus increasing the contractile force of the myocardium, is compatible with the release of norepinephrine from sympathetic nerves within the myocardium. It has been suggested that one of the opioid receptors involved in the myocardium may be localized on presynaptic terminals or sympathetic neurons that innervate the myocardium (Caffrey et al. 1985). Excitation of these receptors in turn inhibits or blocks the release of norepinephrine and depresses myocardial contractility. Administration of naloxone would compete by binding or displacing the opiate peptides from the receptor sites; this would then result in immediate release of norepinephrine and an increase in myocardial contractility.

In the cat, IV naloxone (8 mg/kg/hr) significantly reduces the plasma myocardial depressant factor (MDF) in treatment of hemorrhagic shock (Curtis and Lefer 1980). In addition to decreasing MDF, naloxone also lowers circulating amino nitrogen concentrations and plasma cathepsin D. These findings indicate that naloxone lowers the release of lysosomal enzymes, hinders proteolysis, and prevents toxic factor formation (MDF and cathepsin D) during shock. It appears that naloxone has a dual protective effect through its nonspecific action as well as through its so-called specific opiate antagonist action.

Naloxone (2 mg/kg IV dose followed by continuous infusion of 2 mg/kg/hr) has been used in experimental endotoxemia 3 days postoperatively in the pig; severe metabolic derangement and increased mortality occur (Fettman et al. 1984). In the pony, IV naloxone (1 mg/kg/hr) administered in treatment of endotoxic shock failed to prevent hemodynamic and biochemical alterations (Moore et al. 1983). These studies differ from those that have shown a protective effect of naloxone in the rat, dog, and cat. There is a possibility that a species variation exists with respect to the responsive effects of naloxone in treatment of shock. It may also be possible that higher doses of naloxone are required in the pig and pony before the protective effects of naloxone can be achieved. Additional research will be necessary to clear up these differences.

Other vasoactive substances (histamine, bradykinin, adenosine, leukotrienes, and/or prostaglandin release) besides β-endorphin are involved in shock. Also, the buildup of hypoxanthine and its subsequent conversion to superoxide radicals by xanthine oxidase appear to be prominently involved in irreversible shock (McCord 1985).

A disadvantage in use of naloxone for treatment of traumatic shock is its blockade of the μ_1 opioid receptor, which mediates analgesia. Since the δ receptors are believed to mediate the arterial hypotensive effects of β endorphin, a selective δ-receptor antagonist would ideally be a more efficacious approach in treatment of painful shock; perhaps a selective antagonist for δ opioid receptors will eventually be synthesized for clinical use.

Another antagonist that appears to have potential value in reversing the adverse action of β endorphin upon blood pressure is TRH (Zaloga et al. 1984). Although TRH does not bind to opioid receptors, it is referred to as a physiologic opiate antagonist. It improves survival and reverses arterial hypotension produced by hemorrhagic and endotoxic shock. Synthesis of TRH analogs are now under study for possible use in shock therapy.

ENDOCRINE SYSTEM. Curiously, naloxone can alter expression of the estrogen-induced daily surge signal in ovariectomized rats (Sylvester et al. 1980). It appears that endogenous opioid peptides (enkephalins or endorphins) may possibly play a role in modulating steroid regulation of the neural surge signal for luteinizing hormone (LH) and follicle-stimulating hormone.

Opioid receptor blockade by naloxone elevates serum concentrations of LH in rats and humans. The effect of naloxone on LH secretions is opposite to that induced by morphine or exogenous opiate peptides. Consequently, naloxone appears to antagonize an inhibition of LH release that is mediated by opioid receptors (Blank and Mann 1981).

Injection of naloxone into mother rats just before suckling of their pups results in significant inhibition of growth hormone (GH) and prolactin release (Miki et al. 1981). Inhibition of prolactin release by naloxone is dose related. These findings suggest that the suckling stimulus induces release of endogenous opiate peptides, which in turn are involved in release of GH and prolactin.

In humans, naloxone does not alter basal GH, prolactin, or TRH release; however, it stimulates a significant elevation in cortisol and gonadotropins (Delitala et al. 1981). Infusion of naloxone increases the rate and amplitude of LH pulsatility. Naloxone does not alter the pituitary response to TRH and luteinizing-releasing hormone stimulation. Elevation of cortisol following naloxone administration suggests the presence of an inhibitory opioid influence upon basal ACTH release (Blankenstein et al. 1980). Consequently, it appears that ACTH release is under tonic inhibition by an opioid pathway.

MOTOR BEHAVIORAL EFFECT. In horses, crib biting is a repetitive behavioral characteristic that may involve activation of opioid and dopamine receptors in the CNS (Dodman et al. 1987). Naloxone administered in IV or IM doses (0.02–0.04 mg/kg) prevents crib-biting behavior for 20 minutes after a single injection. Other narcotic antagonists such as naltrexone, nalmefene, and diprenorphine prevent this stereotyped behavior for longer periods (Dodman et al. 1987).

CLINICAL USE. In the dog and cat, one part of naloxone will antagonize respiratory depression produced by 15–20 parts of oxymorphone (Palminteri 1966). The reversal of all actions of oxymorphone, including its analgesic effect, occurs when a ratio of 0.4 mg naloxone to 1.5 mg oxymorphone is administered. Effects of morphine and meperidine are reversed by naloxone to a lesser degree than those of oxymorphone. Naloxone does not antagonize the anesthetic effect of halothane (Harper et al. 1978). Barbiturates, procaine, and tranquilizers also are unaffected by naloxone. No adverse reactions in dogs and cats occur when naloxone is used with ether, methoxyflurane, pentobarbital, thiamylal, procaine, oxymorphone, morphine, meperidine, or many commercially available phenothiazine tranquilizers.

In the dog, naloxone will also adequately reverse the fentanyl component of droperidol-fentanyl (Paddleford and Short 1973). It has no effect in antagonizing the action of droperidol. However, 4-aminopyridine (0.5 mg/kg) administered intravenously in combination with naloxone (0.04 mg/kg) immediately reverses the actions of both droperidol and fentanyl (Booth et al. 1982).

A number of literature sources state that naloxone will reverse the emetic action of apomorphine, a dopamine agonist. Findings by Keith et al. (1981) indicate that naloxone has no therapeutic effect in reversal of apomorphine-induced emesis in the dog.

Naloxone can be administered by all of the parenteral routes; however, the IV route is preferred to attain immediate effect from the drug. Where it is difficult to locate veins, naloxone can be administered intramuscularly at high doses in wild herbivores without overdosages (Smuts 1975). In large wild species, 1 mg naloxone injected intravenously is sufficient to antagonize 1 mg etorphine or 10 mg fentanyl. According to Smuts, naloxone compares favorably with diprenorphine, the antagonist used to reverse action of etorphine; e.g., in the young adult elephant, 10 mg naloxone intravenously is sufficient to antagonize 8 mg etorphine used in combination with various tranquilizing agents.

Respiratory depressant effects of overdosages of oxymorphone in dogs and cats can be reversed with a ratio of 0.1 mg naloxone to 1.5 mg oxymorphone (Palminteri 1966). If the narcotic antagonist is administered intramuscularly or subcutaneously, onset of action occurs in 1–5 minutes; intravenously, onset is immediate and lasts 1–2 hours.

In reversal of narcotic effects of morphine and fentanyl in the dog, 0.016–0.1 mg/0.45 kg naloxone is used intravenously (Paddleford and Short 1973). This quantity of naloxone antagonizes effects of 0.02–0.03 mg/0.45 kg fentanyl administered intramuscularly and 0.01 mg/0.45 kg fentanyl administered intravenously. This same quantity of naloxone antagonizes the effect of 0.5 mg/0.45 kg morphine intravenously.

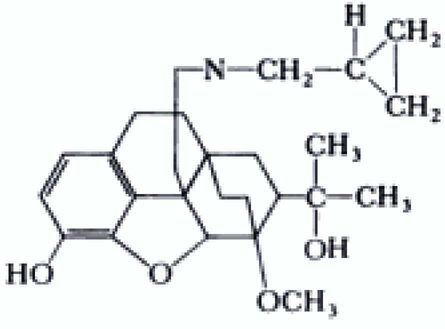
The parenteral dose of naloxone approved by the FDA for the dog is 0.04 mg/kg. When the drug is administered intravenously, this dosage may be repeated at 2- to 3-minute intervals to produce the desired effect.

Naloxone is available in concentrations of 0.02, 0.04, or 1 mg/mL.

Diprenorphine Hydrochloride. Chemically, diprenorphine hydrochloride (Nororipavine, Cyprenorphine, M-285, M50-50, Revivon) is *N*-(cyclopropylmethyl)-6,7,8,14-tetrahydro-7-α-(1-hydroxy-1-methylethyl)-6,14-endo-ethano-nororipavine hydrochloride (Fig. 13.7).

Diprenorphine at double the dosage of etorphine is capable of completely reversing the action of etorphine in wild animals (Alford et al. 1974). Diprenorphine (2 mg/mL) was approved by the FDA in 1973 for use in wild and exotic animals to specifically reverse the effects of etorphine. It is administered intravenously or intramuscularly. Diprenorphine must not be used 30 days before or during the hunting season in free-ranging animals that might be used for human consumption. The drug is subject to the Controlled Substances Act of 1970 (Schedule II).

ADMINISTRATION AND DOSAGE. Prior to administration of diprenorphine, every consideration must be given to dealing with a fully conscious animal in as soon as a few seconds up to 4 minutes after IV injec-



Diprenorphine

FIG. 13.7

tion. Consequently, a safe place should be available to avoid attacks by wild animals upon recovery from etorphine.

Most consistent results are obtained when an etorphine to diprenorphine ratio of 1:2 is used (i.e., 1 mg of etorphine is antagonized by 2 mg of diprenorphine). Reversal of narcotic effects of etorphine is obtained by IV administration of either diprenorphine or naloxone. Residual narcosis after administration of diprenorphine is less than that from nalorphine (Alford et al. 1974). If diprenorphine is administered intramuscularly to reverse the effect of etorphine, 5–20 minutes may be required before CNS depressant effects are reversed.

In horses, diprenorphine (0.02–0.03 mg/kg intramuscularly) prevents crib biting in horses for 4 hours or more (Dodman et al. 1987). Other narcotic antagonists (naloxone, naltrexone, nalmefene, TRH) also prevent this stereotypic behavioral effect in horses.

Diprenorphine (30 μg/kg) is also recommended intravenously for reversal of effects of etorphine (22 μg/kg) when employed in combination with acepromazine for immobilization of the horse (Jenkins 1972).

Diprenorphine rapidly reverses immobilizing effects of etorphine used in combination with acepromazine in the camel; complete recovery occurs 1.5–3 minutes following IV administration (Schels and Nowrouzian 1977). IV use of diprenorphine for reversal of the immobilizing effects of etorphine is usually followed by rapid recovery in most animal species.

Levallorphan Tartrate. *Levallorphan Tartrate,* USP (Lorfan), acts as an antagonist during CNS action of opiate and related analgesics. The CNS effects of these compounds are antagonized or reversed by levallorphan; however, if it is administered in the absence of opiate-derivative analgesics, it usually induces respiratory depression. Consequently, the partial agonist characteristics of the drug are seen.

Levallorphan is ineffective in antagonizing respiratory depressant actions of anesthetics, barbiturates, or nonnarcotic drugs and may even increase the respiratory and CNS depressant effects of these drug classes.

IV administration of levallorphan (0.022 mg/kg) has been used to relieve or prevent the excitable effects of morphine in the horse (Klavano 1975).

Naltrexone. *Naltrexone,* INN (Trexan), is a μ, κ, and δ opioid receptor antagonist (Bailey and Stanley 1994). It has been used experimentally for prevention of crib biting, an aberrant behavioral pattern in horses (Dodman et al. 1987). A single IV dose of 0.4 mg/kg naltrexone prevents biting for 6 hours after administration.

Nalmefene. *Nalmefene,* INN (previously named nalmetrene), is an opioid receptor antagonist similar to naltrexone, with greater preference for μ receptors than for κ or δ receptors (Michel et al. 1988). Nalmefene is also effective in preventing crib biting in horses for 4 hours or more in an IV or IM dose of 0.08 mg/kg (Dodman et al. 1987). The stereotyped biting can be prevented completely by nalmefene for up to 1 week by continuous IV administration of 5–10 mg/kg/hr; crib biting resumes when the infusion is stopped.

Other narcotic antagonists (naloxone, diprenorphine, TRH) will also interrupt or prevent crib biting behavior in horses. Use of narcotic antagonists in the neuropharmacologic management of other stereotypies in the horse and other species has potential value. According to Dodman et al. (1987), captive animals in zoos are potential sources of investigational material because pacing and other forms of repetitive behavior as a result of boredom or stress are commonly observed.

OPIOID PARTIAL AGONISTS

Buprenorphine Hydrochloride. *Buprenorphine Hydrochloride,* USP (Buprenex), is a partial agonist with a very high affinity for the μ opioid receptor but only partial activity. It is a thebaine derivative with a structure similar to morphine but has a lower abuse potential and is classed as a Schedule V drug. It is highly lipophilic but is slow to associate and dissociate from opioid receptors. This results in a slow onset and long duration of action (Bailey and Stanley 1994). The elimination half-life, total body clearance, and steady-state Vd are 2.8 hours, 23.2 mL/min/kg, and 4.2 L/kg, respectively, in the rat (Ohtani et al. 1994). In the dog it is metabolized primarily by glucuronidation, and the principal metabolite, buprenorphine glucuronide, is eliminated almost completely (92%) in the bile (Garrett and Chandran 1990). It is commonly used for postoperative analgesia because of its long duration of action and minimal adverse side effects. Buprenorphine is also often used for analgesia in laboratory animals. The doses (in mg/kg IV, IM, or SC) for various species are as follows: dog and cat, 0.01–0.02; ruminant and swine, 0.005–0.01; rat and mouse, 0.1–1; rabbit, guinea pig, and hamster, 0.05; and horse, 0.01–0.02. The usual dosing interval is 8–12 hours.

Tramadol. *Tramadol Hydrochloride,* USP (Ultram), is a new compound, and its exact mechanism of action is unclear. It appears to be a partial μ agonist. It exhibits very little respiratory depression and abuse potential. An additional analgesia mechanism may involve inhibition of reuptake of norepinephrine and serotonin (Raffa et al. 1992; Driessen and Reimann 1992; Kayser et al. 1992). Lintz et al. (1981) described its biotransformation and excretion in several species. The drug is well absorbed when administered orally and is metabolized via demethylation followed by conjugation. The metabolites are excreted primarily in the urine. Tramadol is metabolized more rapidly in animals than in humans.

OPIOID AGONIST-ANTAGONISTS

Nalbuphine Hydrochloride. *Nalbuphine Hydrochloride,* USP (Nubain), is a semisynthetic opioid with a

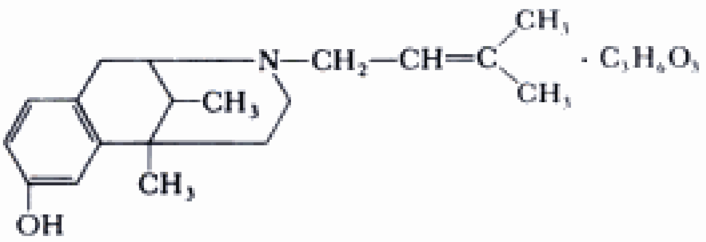


FIG. 13.8

structure similar to oxymorphone. It is an agonist-antagonist that acts primarily as an antagonist at μ receptors and as an agonist at κ receptors. This results in limited analgesia as well as limited respiratory depression. It is metabolized by the liver. Nalbuphine produces minimal cardiovascular changes, leading to its use in human medicine as an analgesia for patients with heart disease and as a reversal agent for the respiratory depression associated with opioid agonist administration (Stoelting 1991). Its use in veterinary medicine has been somewhat limited. Nalbuphine has been shown to produce visceral analgesia in cats (Sawyer and Rech 1987).

Pentazocine Lactate. In the search for antagonists with a benzomorphan structure, pentazocine lactate (Talwin-V) emerged as an analgesic with few side effects. Consequently, it received considerable attention for use in humans because of its potential as a nonaddicting and effective analgesic. However, addictive characteristics were uncovered that dictated placement of pentazocine on the Schedule IV list in 1979.

Chemically, pentazocine is 2′-hydroxy-5,9-dimethyl-2-(3,3-dimethylallyl)-6,7-benzomorphan (Fig. 13.8). Each milliliter of the commercially available preparation contains 30 mg pentazocine. The FDA has approved its use in the horse; in 1982, pentazocine was approved for use in the dog.

PHARMACOLOGIC CONSIDERATIONS. The pharmacologic characteristics of pentazocine are quite similar to those of the opiate compounds. Consequently, the principal effects of the analgesic agent are upon the CNS and smooth muscle. The analgesic potency is approximately one-half to one-fourth that of morphine and is about five times that of meperidine. Pentazocine is an agonist-antagonist, with its primary agonist effect at the κ receptors and weak antagonist activity at the μ receptors (Bailey and Stanley 1994).

FATE AND METABOLISM. The kinetics of disappearance of pentazocine from plasma following an IM injection of 3 mg/kg have been determined in ponies, goats, swine, dogs, and cats (Davis and Sturm 1970). This dose of pentazocine is higher than that employed in humans (i.e., 0.6 mg/kg). However, according to Davis and Sturm, the dosage used in their studies was considerably below the amount reported to induce toxic effects in animals. With exception of the dogs, disappearance of pentazocine from plasma follows first-order kinetics. The peak plasma concentrations after its administration occur at 15 minutes in dogs, goats, and swine; at 30 minutes in ponies; and at 1 hour in cats (Davis and Sturm 1970). The plasma half-life values range from 22 minutes in dogs to 97 minutes in ponies (see Table 13.6).

TABLE 13.6—Kinetic constants for disappearance of pentazocine from blood plasma of domesticated animals

Species	C_o	$t_{1/2}$	$K'd$	$V'd$
	(mg/L)	*(min)*	*(hr⁻¹)*	*(L/kg)*
Ponies	0.59	97.1	0.0071	5.09
Goats	0.52	51.0	0.0136	5.77
Swine	0.63	48.6	0.0143	4.76
Dogs	0.85	22.1	0.0313	3.66
Cats	1.08	83.6	0.0083	2.78

Source: Davis and Sturm 1970.

Note: C_o = plasma concentration of drug at zero time; $t_{1/2}$ = plasma half-life; $K'd$ = apparent first-order disappearance rate constant; $V'd$ = apparent specific volume of distribution of drug.

After IV injection, pentazocine (1 mg/kg) distributes widely in the horse (V′d = 5.7 L/kg) and binds (80%) extensively to plasma proteins (Tobin and Miller 1979). Pentazocine has a relatively slow distribution in the horse. The α phase half-time is 27 minutes and the β phase half-time is about 138 minutes. Following an IM injection of 0.66 mg/kg pentazocine, peak plasma levels are attained in about 30 minutes (Tobin and Miller 1979).

In humans, the plasma half-life of pentazocine is about 2 hours after IV (20–25 mg/70 kg) or IM (45 mg/70 kg) administration (Berkowitz 1971). The peak analgesic effect occurs between 30 and 60 minutes after an IM dose and lasts 2–3 hours. The plasma half-life of pentazocine and duration of action in humans are longer than in domestic animals.

Pentazocine is metabolized in humans to a large degree with little of the unchanged (<5%) or parent compound appearing in the urine. The fate of pentazocine is probably quite similar to that of morphine and its derivatives. Its conjugation with glucuronic acid and excretion as a glucuronide have been established. Trace amounts of pentazocine and its metabolites can be detected in urine for several days after a single administration of the drug.

In the horse, about 30% of a dose of pentazocine is eliminated in urine as a glucuronide metabolite (Tobin et al. 1979). When urine is analyzed for this metabolite, pentazocine can be detected for up to 5 days after administration.

Pentazocine crosses the placenta less readily than meperidine (Mirkin 1975). Fetal blood concentrations of pentazocine/mL are attained in humans at 60% of those observed in maternal blood.

CLINICAL USE. Pentazocine has been restricted primarily to preanesthetic medication because of its lack of profound sedation in animals. According to Soma (1971), use of pentazocine for postanalgesic effect in both small-animal and equine anesthesia is inconclusive. Soma suggested an IM dose of pentazocine in the dog of 1.5–3 mg/kg. However, findings suggest pentazocine is unlikely to induce adverse side effects in dogs when administered intramuscularly at a dose of 2 mg/kg (Cooper and Organ 1977).

The FDA-approved dose of pentazocine in the dog is 1.65–3.3 mg/kg; it is approved for IM use only. According to Miner and Losacco (1984), this dosage produces analgesia for 3 hours in the dog.

In the cat, pentazocine (2.2–3.3 mg/kg by the SC, IM, or IV route) has been used for its analgesic action (Wright et al. 1985). For inducing analgesia in laboratory animals, it is used as follows: mouse, SC dose of 10 mg/kg; rat, SC dose of 10 mg/kg; rabbit, SC or IM dose of 2–5 mg/kg.

In the horse, Soma (1971) indicated that the total IV dose of pentazocine is 200–400 mg. Doses of 6–10 mg/kg in the dog (presumably via the IM route) produce tremors and convulsions reminiscent of morphine-like compounds (Soma 1971). Side effects are also observed in the pony when 2.2–4.4 mg/kg pentazocine are administered intravenously or intramuscularly (Lowe 1969). The side effects consist of incoordination, muscular tremors, hypertonicity of muscles, and hypersensitivity to noise. In one trial, a dose of 3 mg/kg by the IM route caused the animal to fall backward to the floor; it paddled its feet in the lateral recumbent position and in a few seconds returned to the standing position.

The analgesic action of pentazocine in the pony provides a more prolonged and consistent effect than meperidine; duration of analgesia for pentazocine is 48 minutes, and for meperidine it is 21 minutes (Lowe 1969). An IV dose of pentazocine (0.55–1.1 mg/kg) produces analgesia lasting 10–20 minutes; an IM or IV dose of 1.65–2.2 mg/kg produces an analgesic effect varying from 15 to 60 minutes (Lowe 1969).

Pentazocine is used for control of pain caused by colic in horses. The drug is slowly administered intravenously at 0.33 mg/kg. A second dose in the same amount is recommended intramuscularly 10–15 minutes after the first. Use of pentazocine in horses subjected to experimentally induced colic indicates that xylazine is a more effective analgesic (Lowe 1978). Pentazocine has also been used in conjunction with Cloropent and acepromazine for treatment of wounds in horses. For preanesthetic use in horses, an IV dose of 0.9 mg/kg pentazocine is recommended (Muir et al. 1978). It must not be used in horses intended for human consumption.

In the clinical evaluation of pentazocine and meperidine for relief of postoperative pain, a blind study was conducted in the dog by Short et al. (1971). It was concluded that meperidine was more effective than pentazocine for surgery of the extremities and thorax, whereas pentazocine was more effective for ocular surgery. In the case of both pentazocine and meperidine, relief of pain varied most in obtunding moderate pain, but both drugs were comparable in relief of severe pain (Short et al. 1971).

Butorphanol Tartrate. *Butorphanol Tartrate,* USP (Torbugesic, Torbutrol, Stadol), is a central-acting analgesic with both agonist and antagonist properties. It is a morphinan derivative and is chemically *l-N*–cyclobutylmethyl-6, 10αβ-dihydroxy-1,2,3,9,10, 10α-hexahydro-(4*H*)10, 4α-imino-ethanophenanthrene tartrate. The molecular formula is $C_{21}H_{29}NO_2 \cdot C_4H_6O_6$.

Butorphanol is an agonist-antagonist with affinity for both the μ and κ opioid receptors. Its primary effect at the μ receptor is as an antagonist, and at the κ receptor as an agonist.

Butorphanol has narcotic antagonist activity equivalent to that of nalorphine, 30 times that of pentazocine, and one-fortieth that of naloxone. As an analgesic, it is considered to be 4–7 times more potent than morphine, 20 times greater than pentazocine, and 40 times greater than meperidine (Pircio et al. 1976; Vandam 1980). However, these relative potencies must be evaluated in light of the ceiling effect of the agonist-antagonists. In addition to its analgesic action, butorphanol is a potent cough suppressant or antitussive agent.

In 1982, it was approved by the FDA for antitussive use in the dog. Butorphanol was later approved as an analgesic for equine use. It is classified as a Schedule IV drug under the 1970 Controlled Substances Act.

PHARMACOLOGIC CONSIDERATIONS. In the horse, the analgesic effects of butorphanol are dose related, with a duration of analgesia ranging from 15 to 90 minutes (Kalpravidh et al. 1984a). An IV dose of 0.2 mg/kg appears to produce optimal analgesia in the horse. Although side effects such as restlessness, ataxia, and shivering occur at this dosage, the combination of butorphanol with a sedative may be helpful in minimizing them (Kalpravidh et al. 1984a). Combinations containing butorphanol for use in the horse include xylazine 0.66 mg/kg IV with butorphanol 0.03 mg/kg IV or detomidine 2.5–5 μg/kg IV with butorphanol 0.03 mg/kg IV (Muir 1991).

When butorphanol is administered to healthy horses in IV doses of 0.1, 0.2, and 0.4 mg/kg, no significant alteration in heart rate, diastolic aortic pressure, diastolic pulmonary arterial pressure, or cardiac output occurs; however, the systolic arterial pressure significantly increases only in the horses given the 0.2 mg/kg dose (Robertson et al. 1981). Minimal effects upon cardiopulmonary functions also have been observed in the dog after IV doses of 0.1 and 0.4 mg/kg butorphanol (Trim 1983). According to Trim, the sedative effect of butorphanol resembles the sedation produced by equipotent doses of meperidine and pentazocine.

In ponies subjected to experimental pain as induced by superficial and visceral stimuli, butorphanol (0.22 mg/kg intramuscularly) has been compared with the analgesic and behavioral effects of IM doses of flunixin (2.2 mg/kg), levorphanol (0.033 mg/kg), morphine (0.66 mg/kg), and xylazine (2.2 mg/kg) (Kalpravidh et al. 1984b). Interestingly, xylazine produces the best analgesia; analgesic effects for superficial and visceral pain persist 3 and 4 hours respectively. Butorphanol is the next best drug after xylazine in obtunding visceral pain; its duration of effect for 4 hours is similar to that of xylazine in the horse. Flunixin, as anticipated, has no effect upon experimentally induced pain. Since flunixin, like aspirin, inhibits biosynthesis of prostaglandins in inflamed tissue to prevent superficial pain perception, it is more effective in blocking pain from pathologic origins. Levorphanol does not produce analgesia for superficial pain; moderate analgesia for visceral pain lasts for at least 4 hours. Morphine produces good analgesia for pain superficially induced for 30 minutes; a slight analgesic effect for visceral pain lasts for 60 minutes. Motor effects (restlessness as exhibited by pacing, pawing, body swinging, and/or head shaking) are produced by butorphanol, levorphanol, and morphine (Kalpravidh et al. 1984b). They do not occur with xylazine or flunixin.

Muir and Robertson (1985) also observed that xylazine (1.1 mg/kg intravenously) produces the most pronounced visceral analgesia in the horse; it lasts about 90 minutes. This is shorter than the 4 hours reported by Kalpravidh et al. (1984b). These differences are probably related to the dose of xylazine administered as well as to IV versus IM administration. According to Muir and Robertson (1985), butorphanol (0.2 mg/kg intravenously) is the best after xylazine for its analgesic effect (60 minutes) upon visceral pain. This is followed by meperidine (1 mg/kg intravenously) and pentazocine (0.99 mg/kg intravenously) with a duration of analgesia for 30–35 minutes.

In small animals butorphanol is often used as part of a preanesthetic regimen, with or without a tranquilizer, and to control mild to moderate pain. The dose usual ranges from 0.1 to 0.4 mg/kg and can be given SC, IM, or IV. It would appear that the analgesia lasts longer in the cat than in the dog (Hosgood 1990; Sawyer et al. 1991). One advantage of the use of butorphanol in cats is its lack of an excitatory effect. Large doses of butorphanol, infusions of 0.1–0.2 mg/kg/min, resulted in generally inadequate anesthesia and profound cardiovascular depression in dogs (Sederberg et al. 1981). Butorphanol can also be administered orally to small animals: the dose is 0.5–1.0 mg/kg 2–3 times daily (Tranquilli et al. 1989).

SC doses of butorphanol to induce analgesia in the mouse and rat are 5.4 and 23.3 mg/kg respectively (Flecknell 1984).

In humans, it is recommended that the dose of butorphanol be reduced when administered simultaneously with phenothiazine tranquilizers or other CNS depressants.

Much more pharmacologic, toxicologic, and clinical data are needed to determine the efficacy and safety of butorphanol before it can be approved for analgesic use in animals.

Nalorphine Hydrochloride. *Nalorphine Hydrochloride*, USP (*N*–allylnormorphine, Nalline, Lethidrone), is a morphine derivative in which an *N*–methyl group has been replaced with an *N*–allyl group. Although nalorphine is a partial agonist, it antagonizes many of the reactions of morphine and its congeners.

ADMINISTRATION. Nalorphine is available as a liquid (5 mg/mL) and is subject to the Controlled Substances Act of 1970 as a Schedule III drug. It is injected by the SC, IM, or IV route; however, the IV route is preferred to attain immediate effect of the drug. Nalorphine has been approved by the FDA for use in the dog.

ABSORPTION AND FATE. Nalorphine is relatively ineffective after oral administration but is promptly absorbed after SC or IM injection. Biotransformation of nalorphine probably is quite similar to that of morphine because it is also conjugated by liver tissue. The duration of action of nalorphine appears to be briefer than morphine.

ACTION. During the action or effect of narcotics, nalorphine usually acts as a narcotic antagonist. However, in their absence, nalorphine acts like a narcotic and may produce CNS depression and analgesia as a result of its partial agonist activity. Now that naloxone is available, there is practically no justification for use of partial agonists such as nalorphine and levallorphan. Nalorphine does not antagonize mild respiratory depression and may actually aggravate it. Very large doses will paralyze respiration in the dog, but lower dosages have little effect. Nalorphine is not constipative in the dog as morphine is. It has little effect upon the cardiovascular system.

The most prominent antagonist action of nalorphine is in preventing or relieving typical respiratory-depressant activity of morphine and all its derivatives, meperidine, and fentanyl. The analgesic and narcotic actions of diethylthiambutene are terminated by an IV injection of nalorphine. It is ineffective against respiratory depression of barbiturates, and inhalant anesthetics. Nalorphine may increase respiratory depressant effects on nonnarcotic CNS depressants. It does not antagonize the effects of xylazine, a nonnarcotic analgesic.

DOSAGE. One milligram nalorphine is recommended for every 10 mg morphine or 20 mg meperidine for reversal of narcotic effects. For reversal of the effects of etorphine, a ratio of 10–20 mg nalorphine to 1 mg etorphine is required (Alford et al. 1974). The IV route is recommended for administration.

The FDA-approved dose of nalorphine in the dog is 0.44 mg/kg by the IV, IM, or SC route.

TOXICITY. Nalorphine appears to possess about the same toxicity as morphine but provides less relief from pain. The SC injection of 11–22 mg/kg in the dog produces little analgesia.

Caution should be observed to ensure proper dosage of nalorphine. If the first dose fails to reverse or antagonize opioid-type agents, additional doses are contraindicated. In the event of an overdosage of nalorphine, respiratory supportive measures must be instituted, including establishment of a patent airway and oxygen administration. Although no data seem to be available, the partial agonist activity of nalorphine should be antagonized by naloxone.

OPIOIDS AND SPINAL ANALGESIA. Opioids can be administered in the epidural or intrathecal space in an attempt to provide analgesia while minimizing the adverse effects typically seen with opioids. When administered in this manner, they interact with opioid receptors within the spinal cord as well as having some systemic effects. The degree of systemic effect seen is a result of the lipophilicity of the opioid used. Epidural or intrathecal use of the more lipophilic agents has limited advantage over systemic use because the vascular uptake of a spinally administered drug is such that significant systemic effects are seen; the dose required is often similar to the systemic dose; and the short duration of actions necessitates frequent redosing or continuous infusion (Rawal 1993). The more lipophilic agents, such as fentanyl, have a rapid effect but a short duration of action. Less lipophilic agents (e.g., morphine) for example, have a slower onset but a much longer duration. The major difference between the epidural and intrathecal routes is dose. There is a 1:10 to 1:20 ratio in the dose of morphine for the intrathecal route versus the epidural route. In dogs 0.11 mg/kg of morphine administered epidurally gives 6 hours of analgesia (Branson et al. 1993). Epidural buprenorphine (0.001 mg/kg) has also been administered to dogs and cats for analgesia. Epidural morphine (0.11 mg/kg) has been used to control abdominal pain in horses.

OPIOIDS AND PERIPHERAL ANALGESIA. Opioid receptors have been demonstrated on primary afferent nerve fibers, but their function has not been determined (Fields et al. 1980). Recent evidence indicates they may modulate pain transmission via μ and κ receptors, especially when inflammation is present (Stein et al. 1988; Joris et al. 1987).

In the 1950s, phenothiazine derivatives (chlorpromazine, promazine, and others) were introduced into clinical veterinary medicine as ataractics (tranquilizers). Their discoverers coined the term *neuroleptics* to indicate that their most prominent pharmacologic effects are on certain functions of the central nervous system (CNS).

Neuroleptic drugs of major importance in veterinary medicine are the phenothiazines, α_2-adrenergic agonists, and benzodiazepines. Butyrophenones are used infrequently in veterinary medicine. See previous editions of this book for a review of the pharmacology and clinical use of tranquilizers and related agents that are now rarely or no longer used in veterinary medicine.

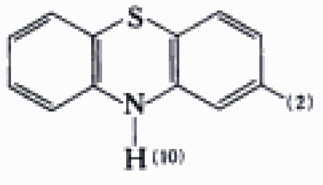
PHENOTHIAZINE DERIVATIVES

The Dopamine Receptor. The principal central activity of the phenothiazine tranquilizers is blockade of the effects of dopamine, a catecholamine CNS neurotransmitter. Dopamine is believed to have primarily inhibitory activity in the brain, with the greatest concentrations in the basal ganglia and the limbic system. A deficiency of dopamine within the basal ganglia has been shown to be associated with a definite dysfunction of this neuroanatomical system, i.e., the Parkinsonian syndrome in humans and catalepsy in experimental animals (Hornykiewicz 1973).

Dopamine exerts its effects through interaction with specific receptors located on the neuronal membrane surface. Postsynaptic neuronal dopamine receptors have been described, but there is evidence suggesting that presynaptic dopamine receptors may also exist. Dopamine receptors are included in the family of G-protein-coupled receptors. Dopamine acts as a *first messenger* by interacting with the receptor proteins of the postsynaptic membrane. This interaction results in transduction of the signal by a guanine nucleotide-binding regulatory protein (G protein) to an appropriate intracellular effector system, or *second messenger.* Three major types of second messengers have been described in the CNS: adenylyl cyclase (cyclic AMP), guanylyl cyclase, and phospholipid hydrolysis (eicosanoid) systems (Cooper et al. 1991).

It was originally believed that stimulation of adenylyl cyclase activity was the principal effect of dopamine. However, inhibition of adenylyl cyclase activity has also been demonstrated with some dopaminergic agonists. This led to the initial classification of dopamine receptors into subtypes D_1 and D_2. Interaction with the D_1-receptor subtype stimulates adenylyl cyclase activity and increases intracellular levels of cyclic AMP; interaction with the D_2 receptor subtype inhibits adenylyl cyclase activity. At present, five mammalian dopamine receptor subtypes have been described and classified into D_1 and D_2 *subfamilies* of dopamine receptors (Lachowicz and Sibley 1997).

Based on hydropathy analysis, the dopamine receptor has been described structurally as seven hydrophobic domains that traverse the plasma membrane. The amino acids in these domains are believed to be in an α-helical configuration. The D_1-receptor subfamily has a relatively small third cytoplasmic loop, which is consistent with stimulatory G-protein-associated receptors. The D_2 receptor subfamily has large third cytoplasmic loops and short carboxyl termini, which are characteristic of inhibitory G-protein-associated receptors (Strader et al. 1989; Dohlman et al. 1991).



Phenothiazine

FIG. 14.1

The D_1 subfamily includes the traditional D_1 subtype (also referred to as D_{1A}) and the D_5 receptor (also referred to as the D_{1B} receptor). Both the D_1 and D_5 receptors bind dopaminergic agonists and antagonists with similar affinity but differ in primary amino acid sequence and anatomical distribution (Lachowicz and Sibley 1997). There is a high degree of structural homology between the D_{1A}/D_1 and D_{1B}/D_5 receptor subtypes, although dopamine binds to the D_{1B}/D_5 receptors with a five- to tenfold greater affinity than to the D_1 receptor (Grandy et al. 1991; Monsma et al. 1991; Sunahara et al. 1991; Tiberi et al. 1991; Weinshank et al. 1991).

The D_2 subfamily includes D_3 and D_4 receptor subtypes, as well as the traditional D_2 receptor subtype, which has been isolated into short (D_{2S}) and long (D_{2L}) isoforms (Lachowicz and Sibley 1997). In addition to adenylyl cyclase inhibition (Neve et al. 1989), the D_2 receptors potentiate a variety of signal transduction pathways, including stimulation of arachidonic acid release (Kanterman et al. 1991), phosphatidylinositol hydrolysis and mobilization of calcium (Vallar et al. 1990), regulation of K^+ channels (Einhorn et al. 1990; Liu et al. 1994, 1996), and suppression of prolactin release (Albert et al. 1990). The D_2 long isoform receptor contains a 29 amino acid sequence that is missing from the D_2 short receptor. The two isoforms share similar pharmacological profiles and functional abilities, although they may act via different G proteins in mediating adenylyl cyclase inhibition (Dal Toso et al. 1989; Senogles 1994) and regulation of potassium channels (Einhorn et al. 1990; Liu et al. 1994, 1996). It has been suggested that the 29 amino acid sequence may function to direct the isoforms along different regulatory pathways (Lachowicz and Sibley 1997).

The pharmacological profile of the D_3 receptor is similar to that of the D_2 receptor (Sokoloff et al. 1990; Freedman et al. 1993; Malmberg et al. 1993; Mackenzie et al. 1994). D_3-receptor-mediated adenylyl cyclase inhibition has been reported to be minimal compared to that of the D_2 receptor (Castro and Strange 1993; Seabrook et al. 1992; Chio et al. 1993). However, other D_3-receptor-mediated effects have been identified, and it has been suggested that these effects may be mediated by a second-messenger system that has yet to be described (Lachowicz and Sibley 1997). Most dopaminergic agonists bind with greater affinity to the D_3 receptor, whereas most antagonists bind with greater affinity to the D_2 receptor (Sokoloff et al. 1990, 1992).

Binding properties of the D_4 receptor resemble those of the D_2 receptor, although most dopaminergic agonists and antagonists bind to the D_2 receptor with greater affinity than to the D_4 receptor (Van Tol et al. 1991; O'Malley et al. 1992; Asghari et al. 1994; Chabert et al. 1994; Tang et al. 1994). An exception is clozapine, a highly effective antipsychotic drug used in human patients. Clozapine is a dopaminergic antagonist that binds preferentially to D_4 receptors, with an affinity that is about tenfold greater than its affinity for D_2 receptors (Coward 1992). Clozapine is not associated with extrapyramidal effects that may occur with the blockade of D_2 receptors in the basal ganglia nuclei. As there appears to be a greater concentration of D_4 receptors in limbic nuclei than in the basal ganglia nuclei, this has led to the hypothesis that the D_4 receptor may be the therapeutic target for antipsychotic drugs (Lachowicz and Sibley 1997).

General Pharmacologic Considerations. Phenothiazine is the parent compound for all the derivatives in this group (Fig. 14.1). Substitution is made primarily in the phenothiazine nucleus at the 2 and 10 positions.

The majority of pharmacologic actions discussed for phenothiazines pertain to chlorpromazine hydrochloride. However, the mechanisms of action for other phenothiazines are similar to chlorpromazine except for variations primarily referable to potency and duration of action. In clinical practice, greater potency of a drug does not necessarily imply greater effectiveness. This is true of phenothiazines because controlled investigations have been unable to show any significant difference in effectiveness of these agents when administered in equipotent doses.

All phenothiazines exert a sedative action by depressing the brain stem and connections to the cerebral cortex but may vary in potency and duration of action. Unlike barbiturates, the sedative effect does not appreciably affect coordinated motor responses, and arousal is easily accomplished. If a piperazine structure is linked to position 10 of the molecule, reduced or no sedative action is observed (as with prochlorperazine).

All phenothiazines decrease spontaneous motor activity in animals. At high doses, cataleptic effects may be produced so that animals will remain immobile in a fixed position for long periods. Extrapyramidal symptoms (rigidity, tremor, akinesia) are also observed as prominent side effects of phenothiazines in animals administered high doses.

Most phenothiazine derivatives increase the rate of dopamine turnover (i.e., synthesis and destruction) in the brain (Hornykiewicz 1973; Matthysse 1973). Moreover, there is an increased turnover of norepinephrine. This effect may be related to the potency of these compounds in eliciting extrapyramidal symptoms (catalepsy) in animals. Chlorpromazine and other phenothiazines that have been observed to produce extrapyramidal symptoms also increase the synthesis and destruction of dopamine (Matthysse 1973); chlorpromazine increases the concentration of the dopamine metabolite homovanillic acid in the caudate nucleus of the cat and rabbit. Conversely, the prototype phenothiazine derivative, promethazine, has antihistaminic activity and does not increase the concentration of homovanillic acid or affect the synthesis and destruction of dopamine. Trimeprazine tartrate, a nonpsychotropic phenothiazine, produces a slight increase in the dopamine metabolite level within the corpus striatum of the rabbit.

In addition to blockade of the central effect of catecholamines (e.g., dopamine), phenothiazines are known to block peripheral actions of catecholamines. Chlorpromazine and other related compounds can prevent and reverse a number of actions of epinephrine (epinephrine reversal). Since α-adrenergic receptors are blocked by chlorpromazine and related derivatives, the β-adrenergic receptors are stimulated by the potent β component of epinephrine; this results in vasodilation and/or arterial hypotension and may induce shocklike conditions. Administration of epinephrine is contraindicated whenever phenothiazine derivatives are used. However, norepinephrine can be used without risk of aggravating arterial hypotensive effects of phenothiazines, because of its weak β-agonist action compared to epinephrine. It has been suggested that the major action of the phenothiazines may be stimulation of β_2 receptors (vasodilation) rather than blockade of α receptors. However, most pharmacologists indicate that phenothiazines block α-adrenergic receptors, which then results in vasodilation or hypotension. Regardless of mechanism, chlorpromazine and most other phenothiazine derivatives cause arterial hypotension. Phenothiazines are contraindicated in regional (epidural and intrathecal) anesthetic procedures because they potentiate the arterial hypotensive effects of local anesthetics.

Chlorpromazine and, to a lesser degree, acepromazine maleate prevent epinephrine-induced ventricular fibrillation during use of halogenated anesthetics (halothane, methoxyflurane, and others) similar to α-adrenergic blocking agents. Chlorpromazine has antidysrhythmic activity, implying that it protects the heart from the β_1-receptor stimulant effects of epinephrine and norepinephrine. However, the direct depressant effect of chlorpromazine upon the myocardium may be the actual mechanism that prevents the dysrhythmic effects of catecholamines.

Morphine-induced hyperexcitement and manic behavior in the cat can be prevented by pretreatment with chlorpromazine (Dhasmana et al. 1972). It is believed that morphine sulfate enhances release of dopamine in the CNS, which in turn stimulates central dopaminergic receptors to induce the manic response. Moreover, morphine appears to increase norepinephrine release, which may also result in CNS excitation in the cat.

Unlike morphine and its derivatives, the phenothiazine derivatives have little or no analgesic activity. Tranquilization must be supplemented with analgesics and/or general anesthetics to block nociceptive responses during painful procedures.

Hypothermic effects appear to be induced by phenothiazines as a result of depletion of catecholamine substances within the hypothalamus, where thermoregulation is controlled centrally.

Chlorpromazine affects pituitary activity only in quantities that exceed those required to induce depressant effects (de Wied 1967). At high doses, chlorpromazine appears to block release of the follicle-stimulating hormone and luteinizing hormone. Ovulation is blocked and the estrous cycle is suppressed. It has been shown that chlorpromazine, acepromazine, and perphenazine increase the plasma level of prolactin in a number of species (i.e., rat, sheep, goat, human) (Blackwell et al. 1973). An increase of plasma prolactin can result in galactorrhea. Other endocrine effects include inhibition of release of the melanocyte-stimulating hormone and antidiuretic hormone and inhibition of oxytocin release.

Hyperglycemia has been observed following administration of chlorpromazine and other phenothiazines in several species, including humans. The principal mechanism of phenothiazine-evoked hyperglycemia is believed to be release of epinephrine via the adrenal medulla; this in turn mobilizes liver glycogen. Inasmuch as the relative effectiveness of phenothiazines in elevating blood glucose does not correlate well with their capability to stimulate secretion of adrenal catecholamine, questions arise about the actual mechanism(s) involved. Phenothiazines do indeed elevate blood glucose through release of epinephrine from the adrenal medulla because extirpation of the adrenal medullae abolishes or reduces the glycemic responses. However, extra-adrenal mechanisms are also involved and appear to be more important in the overall effect upon blood glucose; e.g., inhibition or blockade of the effect of insulin is a major factor in determining the degree of hyperglycemic effect produced by certain phenothiazines (Proakis and Borowitz 1974).

Chlorpromazine and other phenothiazines have a paralyzing action upon skeletal muscle similar to that produced by *d*-tubocurarine. Chlorpromazine's action can be antagonized to some extent by eserine or neostigmine.

Amphetamine, an excitatory dopamine receptor agonist and many sympathomimetic compounds structurally similar to catecholamines are blocked centrally by phenothiazine derivatives. In amphetamine overdosage, chlorpromazine is recommended as one of the antidotes for treatment of CNS excitation and convulsions. Serotonin is also blocked by chlorpromazine. In addition, it blocks the locomotor hyperactivity and stereotyped motor behavior evoked in animals by apomorphine, a potent dopamine agonist (Hornykiewicz 1973). The antiemetic activity of chlorpromazine and other phenothiazines is related to blockade of dopamine receptors of the chemoreceptor trigger zone within the medulla (DiChiara and Gessa 1978). Emetic stimulant effects of ergot alkaloids are also inhibited by chlorpromazine.

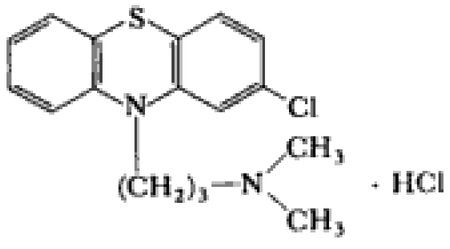
Although phenothiazine tranquilizers will antagonize the CNS-stimulating effects of sympathomimetic amines (e.g., amphetamine and related drugs), they do not prevent the convulsive action of strychnine, pentylenetetrazol, and picrotoxin. Phenothiazines in therapeutic doses suppress conditioned avoidance behavior, inhibit spontaneous motor activity, and reduce aggressive behavior and hostility. At higher doses, interference with locomotor function is observed. Moderate doses produce sedation and drowsiness; in larger concentrations, phenothiazines induce ataxia and somnolence.

Clinical levels of phenothiazines ordinarily have little effect upon respiratory activity. If arterial hypotension occurs, respiratory activity may be reflexly accelerated through decreased activity of the carotid and aortic pressoreceptors. Large doses, however, will depress respiratory activity. Vasomotor activity controlled via the hypothalamus or at the medullary level is depressed by low levels of chlorpromazine.

Chlorpromazine and other phenothiazines markedly reduce the hematocrit of animals. At one time the mechanism was thought to be related to a hemodilution effect or an increased plasma volume. However, reduction in the hematocrit or packed-cell volume (PCV) by the phenothiazines is believed due to splenic sequestration of red blood cells, and blood samples drawn from phenothiazine-treated animals for diagnostic purposes should be interpreted accordingly.

Chlorpromazine Hydrochloride. Chemically, *Chlorpromazine Hydrochloride*, USP (Thorazine, Largactil), is 2-chloro-10-(3-dimethylaminopropyl)-phenothiazine (Fig. 14.2). In the hydrochloride salt form, it is a grayish white crystalline powder that is very soluble in water. Although it decomposes in light, it can be boiled without decomposition. Chemical synthesis of chlorpromazine soon followed the observation that an antihistaminic agent (i.e., promethazine), also a phenothiazine compound, produces CNS depression. Chlorpromazine has slight antihistaminic activity.

PHARMACOLOGIC CONSIDERATIONS. Interestingly, the stereochemical model of chlorpromazine is similar to the structures of epinephrine, norepinephrine, and dopamine. This similarity is inapparent when only the two-dimensional structures are compared. Thus, chlorpromazine interacts with both the dopamine and norepinephrine receptors.



Chlorpromazine Hydrochloride

FIG. 14.2

The hypothermic mechanism and other effects of chlorpromazine are difficult to understand because the drug interferes with several neuronal pathways in the brain (Lin 1979); e.g., chlorpromazine blocks the central catecholamine receptors and elevates brain levels of these amines (dopamine, serotonin, norepinephrine). Additionally, the peripheral cholinergic-blocking activity, adrenergic-blocking activity, adrenergic activity, antihistaminic effects, and antitryptaminergic effects of chlorpromazine further complicate understanding of these mechanisms. Nevertheless, it appears that brain monoaminergic systems have a functional role in eliciting or modulating chlorpromazine-induced hypothermia; e.g., depletion of serotonin brain concentrations, as well as depression in activity of this neurotransmitter, appears to augment chlorpromazine-induced hypothermia (Lin 1979).

Other important effects of chlorpromazine apart from its central influences are its adrenergic blocking action in conjunction with weak anticholinergic, antihistaminic, and antispasmodic effects. Chlorpromazine also potentiates the effect of atropine sulfate, analgesics, hypnotics, and local and general anesthetics. Although the blocking effect of local anesthetics is enhanced by chlorpromazine, its use is contraindicated in regional (epidural and intrathecal) anesthetic procedures due to potentiation of arterial hypotensive effects of local anesthetics.

In the dog, but not in the cat, chlorpromazine is effective in antagonizing apomorphine-induced emesis. It also protects against vomiting induced by morphine but is ineffective against IV copper sulfate, digitalis glycosides, veratrum, and oral copper sulfate. The antiemetic effect of chlorpromazine in dogs is related to selective depression of the emetic chemoreceptor trigger zone located in the brain stem. Chlorpromazine in a dose of 0.5 mg/kg is used for antiemetic action in the dog; the route of administration was unspecified by Willard (1985). It was probably given parenterally (i.e., by the intramuscular or intravenous route).

Paradoxically, chlorpromazine is an antidysrhythmic agent by preventing the stimulant effects of epinephrine and norepinephrine upon the heart. However, cardiac dysrhythmias are induced in the unanesthetized and anesthetized dog by either chlorpromazine or promazine in parenteral doses ranging from 2.5 to 5 mg/kg (Santos-Martinez et al. 1972). Atropinization reverts the dysrhythmia to characteristic anticholinergic effects such as sinus and atrial tachycardia.

Effects of chlorpromazine upon metabolism and autonomic nervous activity under conditions of environmental temperature changes and other types of stress have been the target of many studies. In transportation of animals to abattoirs for slaughter, this so-called antistress effect of neuroleptics was investigated to reduce weight losses (shrinkage) and bruising in transport. This use is not approved by the US Food and Drug Administration (FDA) because of the possibility that tissue residues will persist above the accepted tolerance levels permitted in food for human consumption.

High doses of chlorpromazine in the cat produce tremors of one or more extremities or the head. Variable degrees of shivering, lethargy, relaxation of the anal sphincter, diarrhea, and diminution or loss of righting reflexes occur. Rigidity of extremities and trunk without evident alteration in postural and righting reflexes may also occur in the cat. Upon discontinuance of medication, rigidity and other side effects disappear within 10 days, and the cat appears to be fully recovered and normal.

In the horse, chlorpromazine produces undesirable effects in many animals and is no longer advocated in equine practice. After a few minutes of initial sedation following administration of the drug, the animal becomes unsteady, sinks backward on its hocks, and then lunges forward in an uncoordinated manner. The horse may stumble and fall, then stand and continue lunging and rearing. This violent reaction alternates with periods of sedation.

Experimentally, chlorpromazine induces significant antisecretory activity in the intestinal tract; it apparently inhibits intracellular calmodulin activity (Willard 1985). In piglets with experimental colibacillosis induced by *Escherichia coli* toxins, intramuscular (IM) chlorpromazine (1–5 mg/kg) significantly decreases intestinal fluid losses and shortens duration of diarrhea.

ADMINISTRATION. In most species, chlorpromazine is administered primarily by the IM and intravenous (IV) routes. IM injections are slower, somewhat irritating, and less reliable in action. In the rabbit, IM injection of chlorpromazine produces severe myositis, lameness, swelling, muscular atrophy, and paralysis. IM use of this drug is contraindicated in the rabbit for preanesthetic medication (Bree et al. 1971).

METABOLISM AND ELIMINATION. Chlorpromazine is metabolized slowly in the dog. The biologic half-life is about 6 hours. In humans, and probably in the dog, hydroxylation in the 3 and 7 positions and conjugation with glucuronic acid represent the major metabolic pathways in degradation of chlorpromazine. Sulfoxide is the next important product of metabolic biotransformation of chlorpromazine. The sulfoxide form possesses about one-eighth the sedative action of the parent drug in the dog.

In mental patients, chlorpromazine and various metabolites may be detected in urine 6–18 months after termination of treatment (Jarvik 1970). In food-producing animals, drug residues may possibly persist in edible tissues for long periods; information on this subject is lacking.

Chlorpromazine stimulates hepatic microsomal enzyme activity in the rat (Aurori and Vesell 1974). Its administration for 3 days stimulates ethylmorphine *N*-demethylase activity to 135% of control values. Stimulation of both aniline hydroxylase activity and cytochrome P-450 content to levels of 150% of control values occurs following 3 days of treatment with chlorpromazine or promazine hydrochloride.

Little or no chlorpromazine is eliminated in urine of the dog. The primary excretory product is chlorpromazine sulfoxide, but only 10–15% of the dose is eliminated as such. In other species, there is little information about excretion patterns of chlorpromazine and its metabolites.

Limited studies of excretion patterns have been conducted in the horse following IM and oral administration of chlorpromazine (Weir and Sanford 1972). After IM injection, metabolites are detected in urine up to 96 hours. Following oral administration, metabolites are no longer detected after 80–96 hours. The percentage of the dose recovered in equine urine is low, with the average being 10% after IM and 27% after oral administration. Unconjugated metabolites excreted in the horse represented only 1–1.5% of the dose after either route of administration; these were excreted entirely as sulfoxide derivatives. Glucuronide-conjugated metabolites are predominantly excreted by the horse in a ratio to unconjugated metabolites of approximately 7:1 after IM injection and 18:1 after oral administration. Sulfate-conjugated metabolites make up about 5% of the total after oral administration but are detected only in trace amounts after IM injection. With use of spectroscopic analytical methodology, phenothiazine derivatives in the feces of horses are not detected (Weir and Sanford 1972).

In the goat, the concentration of chlorpromazine is higher in milk than in plasma (Nawaz and Rasmussen 1979). Renal clearance of chlorpromazine in goats is low due to extensive plasma protein binding (91–99%). The plasma elimination half-life of chlorpromazine (2.5 mg/kg) given as a single IV dose in the goat is 1.51 ± 0.48 hours (Nawaz 1981). It is suggested that a satisfactory IV regimen of chlorpromazine in the goat should be 2–3.5 mg/kg; this should produce a drug action lasting 5–6 hours.

CONTRAINDICATIONS AND PRECAUTIONS. Administration of epinephrine is contraindicated whenever phenothiazines are used. Phenothiazine derivatives are contraindicated in epidural anesthetic procedures because they potentiate arterial hypotensive activity of local anesthetics. Their use in control of strychnine, pentylenetetrazol, and picrotoxin convulsive seizures is contraindicated because of their ineffectiveness. Additionally, phenothiazine derivatives lower the seizure threshold and increase intracranial pressure, particularly in patients with severe facial trauma (Short et al. 1984). Also, phenothiazines must not be used in patients with a history of seizures or if CNS excitation is present after traumatic episodes.

Package inserts of drug firms caution against use of phenothiazines when animals have been exposed to organophosphates because they may potentiate toxicity of the organophosphates. Repeated administration of chlorpromazine and promazine increases toxicity of parathion in the rat. The anthelmintic phenothiazine does not seem to potentiate toxic effects of organophosphates such as malathion, coumaphos, ronnel, crufomate, dichlorvos, and others (Schlinke and Palmer 1973). In addition, caution against use of phenothiazines in conjunction with procaine hydrochloride is listed on package inserts; the activity of procaine may also be potentiated.

Use of chlorpromazine alone in the horse is contraindicated because of violent incoordination and excitement that often occur following administration. In the air transport of horses, administration of phenothiazines appears to be contraindicated because of variable effects that may be produced, such as incoordination, anxiety, and excitement.

Precautions in use of phenothiazine derivatives include their careful use in debilitated and cardiac disease patients. Caution must be taken in animals suffering from hypovolemic shock as well as those that have sympathetic blockade following epidural anesthesia.

Mixing glycopyrrolate in the same syringe with phenothiazine derivatives or diazepam is contraindicated (Short et al. 1984).

TOXICITY. In the dog, a subcutaneous (SC) dose of 1.5 mg/kg chlorpromazine produces no gross signs of toxicity. However, when the dose is administered intravenously, moderate depression and ataxia occur, which last 6–12 hours. When an IV dose of 3 mg/kg is injected, marked CNS depression and ataxia are noted for 24–48 hours.

The toxicity of physostigmine and dichlorvos are increased by chlorpromazine (Michalek and Stavinoha 1978). Physostigmine is a carbamate anticholinesterase agent, and dichlorvos is an organophosphate compound that inhibits cholinesterase activity. In vitro, chlorpromazine is a weak inhibitor of specific acetylcholinesterase and a rather potent inhibitor of pseudocholinesterase. Inhibition of cholinesterase by phenothiazine derivatives is reversible; it is not reversible when the enzyme is inhibited by organophosphates.

In vivo, chlorpromazine potentiates toxicity of the herbicide paraquat (Siddik et al. 1979). The potentiating mechanism of increased toxicity remains unknown.

Chlorpromazine in high doses produces cleft lip and cleft palate in mouse fetuses (Walker and Patterson 1974). The mouse appears to be more susceptible than the rat or rabbit to teratogenic effects of phenothiazine derivatives (Szabo and Brent 1974). Of six phenothiazine derivatives administered to the rabbit, none induced teratogenic or structural malformations in fetuses. Pregnant mice treated with high doses of phenothiazines eat less and gain less weight. Interestingly, limitation in food and water consumption of pregnant mice to a similar degree while receiving phenothiazines leads to an even higher incidence of cleft palate. Maternal nutritional deprivation results in retardation of fetal growth and may also affect development of the palate adversely (Szabo and Brent 1974). This raises the possibility that other drugs capable of inducing teratogenic effects in the mouse act principally by reduction in food and water intake; thus the embryopathy may be a secondary effect.

Limited studies in the rhesus monkey indicate that phenothiazines do not induce cleft palate or any other congenital defect. In domestic animals, data are lacking regarding effects of phenothiazines on pregnancy and fetal development. Clinical experience in domestic animals indicates that phenothiazine derivatives do not produce structural anomalies during fetal development. However, caution should be exercised in use of these agents during pregnancy; e.g., behavioral teratogenic effects appear to be produced in offspring (rats) that have been exposed perinatally to chlorpromazine (Taub and Peters 1978). Chlorpromazine given to newborn rats produces long-lasting alterations in serotonin and 5-hydroxyindoleacetic acid levels in several brain regions. It is not known to what extent these alterations may affect temperament, learning ability, neurologic activity, or other functions in adulthood.

In the Beagle and American Foxhound, chlorpromazine given orally at 30 mg/kg/day produces ocular lesions within 73 days in both breeds, whether exposed to natural daylight or maintained under ultraviolet-free artificial light (Barron et al. 1972). In the Beagle, an irreversible retinopathy can be induced in less than 4 months following daily oral doses of 30 mg/kg chlorpromazine (Mason 1977). Granular corneal deposits are produced by chlorpromazine and persist for many weeks in the dog even after withdrawal or discontinuance of treatment.

In mice, ocular lesions (toxic retinopathy) are not seen in albino animals following chlorpromazine administration. The retinopathy is related to affinity of chlorpromazine for melanin structures of the eye. In pregnant mice, radiolabeled chlorpromazine rapidly crosses the placenta and accumulates in the eyes of both fetuses and mothers (Ullberg et al. 1970). Marked radioactivity remains in tissues of the eye for 5 months after the drug had been eliminated from other tissues.

Clinically, phenothiazines are used intermittently and usually do not entail a protracted period of therapeutic use in veterinary medicine. The likelihood that ocular lesions would develop under short-term therapeutic use is improbable.

Experimental phototoxicity can be induced in laboratory animals following administration of chlorpromazine in the presence of black-light irradiation (Akin et al. 1979). Although phototoxic reactions in animals do not appear to be an important clinical problem, those with scanty hair and white hair probably should not receive excessive exposure to sunlight during treatment with phenothiazines.

CLINICAL USE

DOGS AND CATS. Chlorpromazine is approved as a prescription item by the FDA for use only in the dog and cat. At one time, chlorpromazine was the most extensively used neuroleptic agent in these species; however, promazine and acepromazine are now preferred.

Clinically, chlorpromazine has been used in the dog and cat at 0.55–4.4 mg/kg by IV injection for immediate effect. The sedative effect is especially helpful in nervous or aggressive animals. By the IM route of administration, the dose recommended is 1.1–6.6 mg/kg. The oral dose recommended consists of 1 tablet containing 10 mg/3.2 kg or 1 tablet containing 25 mg/7.7 kg. For all routes of administration (IV, IM, oral), chlorpromazine is administered 1–4 times daily, depending on the size of the dose used within the ranges given and needs of the patients.

For preanesthetic purposes, chlorpromazine should be injected intramuscularly 1–1.5 hours prior to anesthesia for surgery at a dose not to exceed 1.1 mg/kg. Clinical effects are prominent for 4–5 hours, but total action may persist for 24 hours. Premedication with chlorpromazine decreases the amount of barbiturate anesthetic (thiopental sodium) required to produce anesthesia by approximately 50% but does not alter duration of anesthesia (Hatch 1967). However, the combination of atropine and chlorpromazine has been shown to reduce the amount of thiopental needed by about 50% but increases sleep time by 33%.

The most consistent clinical effects of chlorpromazine premedication include drowsiness and disinclination to move. When aroused, the animal takes a normal interest in its surroundings. Body temperature may fall several hours later. The pulse rate does not change appreciably nor is respiration markedly depressed.

A claim has been made that chlorpromazine has antiemetic action in the cat and dog. This is questionable in the cat because chlorpromazine fails to inhibit apomorphine-induced emesis; in the dog, chlorpromazine does prevent emesis induced by apomorphine. However, emesis is not prevented by chlorpromazine in animals that are subjected to vestibular stimulation.

FOOD-PRODUCING SPECIES. Use of phenothiazines in food-producing animals has not been approved by the FDA because of the possibility that residues may persist in edible tissues such as meat, milk, and eggs. A tissue tolerance level for chlorpromazine has not been published, but one has been published for promazine.

Chlorpromazine (0.2 mg/kg) administered intramuscularly is considered to be the drug of choice of the neuroleptic agents for preanesthetic use in cattle (Bowen 1976).

BREEDING ANIMALS. Chlorpromazine is sometimes used in animals not scheduled for food use or slaughter, e.g., for breeding. The pig is easily restrained for IV injections 45–60 minutes following IM administration (1.1 mg/kg). Prior to induction of anesthesia with barbiturates, an IM dose of 2–4 mg/kg has been used.

Chlorpromazine is recommended in excitable sows following farrowing, especially in those reluctant to accept their newborn. IV doses of 75–100 mg have been used in sows weighing 125–136 kg. If the drug is used immediately prior to parturition, the sow will farrow naturally. To prevent venous thrombosis, chlorpromazine should be given in dilute solution when it is used intravenously (Jones 1972). Chlorpromazine has been useful as an adjunct to treatment of agalactia, which is a frequent clinical problem following parturition in swine (Lewis and Oakley 1971).

EXOTIC SPECIES. Chlorpromazine has been used in capture of African lions and as an adjunct to restraint and anesthesia in lions (Harthoorn et al. 1971). For induction of neuroleptanalgesia in bears, the drug is administered via a projectile syringe dart in combination with analgesic preparations (Kuntze 1967). Neuroleptics are effective agents in zoo practice; IM doses of chlorpromazine recommended for several species are as follows:

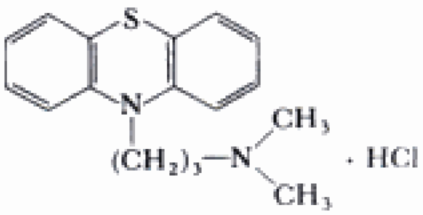
Species	*Dose (mg/kg)*
Tiger	4.0
Jackal	2.0
Bear	2.5
Rhesus monkey	1.4–2.0
Dromedary	1.5–2.5
Water buffalo	2.5
Bison	2.5

Chlorpromazine has been used in reptiles intramuscularly (10 mg/kg) prior to barbiturate anesthesia (Calderwood 1971).

Promazine Hydrochloride. Chemically, *Promazine Hydrochloride*, USP (Sparine), is 10-(3-diethylaminopropyl) phenothiazine monohydrochloride (Fig. 14.3). It is used in the hydrochloride form, and 1 g is soluble in about 3 mL water. The drug is incompatible with alkalies, heavy metals, and oxidizing agents.

Although promazine has been used in nearly all domestic animals, monkeys, and small laboratory rodents, it is approved by the FDA for use only in the dog, cat, and horse. Promazine cannot be used in animals intended for food; a zero tolerance has been established in tissues of food-producing animals.

ADMINISTRATION. Following IV administration of promazine, the onset of action in the dog is generally within 5 minutes; following IM injection, about 20–30 minutes elapses before effective tranquilization results. Onset of action may be 5–10 minutes slower in large species. Duration of action is dose dependent and can vary within 4–6 hours.



Promazine Hydrochloride

FIG. 14.3

METABOLISM AND ELIMINATION. Excretion patterns of promazine have been studied in the horse (Weir and Sanford 1972). When 10 mg/kg are given orally, the excretion rate reaches maximums of about 55 mg/hr within 8 hours of dosing and about 25 mg/hr between 16 and 24 hours. Metabolites cannot be detected in urine after 72 hours (Weir and Sanford 1972). The percentage of promazine recovered in urine averages 10%. Glucuronide-conjugated metabolites are predominant; conjugated metabolites are excreted almost entirely in the form of sulfoxide.

Following IM administration of 0.1–0.6 mg/kg promazine, Maylin (1978) detected four metabolites in urine of Standardbred mares; the metabolites were 2,3-hydroxypromazine, promazine *N*-oxide, promazine *N*-oxide sulfoxide, and 5,3-hydroxynorpromazine.

CONTRAINDICATIONS AND PRECAUTIONS. In general, contraindications described for chlorpromazine apply to promazine. However, unlike chlorpromazine, promazine can be administered to horses with less likelihood of producing excitation. Some animals may be unusually reactive to noise and may respond violently to disturbances.

Caution must be taken to avoid intracarotid injection of promazine; otherwise the horse may become violent and exhibit muscular tremors, stertorous respiration, and pupillary dilation; eventually recumbency and convulsions appear (Christian et al. 1974). Large-caliber needles, especially 14 or 16 gauge, favor pulsatile flow of arterial blood, whereas smaller-bore needles do not, with the result that walls of the external jugular vein are easily passed through and the external carotid artery is inadvertently penetrated with small-bore needles.

CLINICAL USE

DOGS. The major use of neuroleptics, including promazine, is as a preanesthetic agent to facilitate handling through its sedative action. This permits smoother induction of anesthesia and reduces the amount of anesthetic required by 30–50%. In the dog, the dose recommended by the parenteral routes (IM or IV) is 2–6 mg/kg. For antiemetic use, the above dose should be reduced by one-third to one-half (Leash 1969). Promazine may be repeated as necessary at 4- to 6-hour intervals.

Promazine is indicated in animals manifesting nervous behavior and excitability. It has value in alleviation of self-inflicted mutilation associated with otitis, pruritis, and eczemic conditions. The drug assists in handling of animals for radiographic diagnosis or therapy and in other procedures where restraint is required.

Promazine (6.6 mg/kg IV) has been used for cesarean section in 1- to 6-year-old Beagles in conjunction with infiltration of 6 mL 2% lidocaine hydrochloride or mepivacaine hydrochloride into the abdominal wall (Gupta et al. 1970). If this dose of promazine does not produce complete relaxation, more is given subcutaneously at the rate of 2.2–4.4 mg/kg for the latent effect during surgery. Of the puppies delivered by this procedure, Gupta et al. reported that 98% lived and nursed with no signs of tranquilization. The oral dose of promazine recommended in dogs and cats is 2.2–6.6 mg/kg every 4–6 hr.

CATS. Clinical indications and recommended parenteral dosage for the cat are similar to those for the dog. Compared to chlorpromazine, twice as much promazine is generally required to produce a comparable effect in the cat. Arterial hypotension and other cardiovascular effects produced by promazine in the cat are considerably less than those of chlorpromazine (Clifford and Soma 1969).

One of the therapeutic claims made for promazine is that its administration before a vermifuge will prevent emesis in the cat. This is debatable because studies have shown that a related congener, i.e., chlorpromazine, fails to antagonize emesis induced by apomorphine in cats.

A combination of promazine and ketamine hydrochloride has been advocated for use in the cat (see clinical use of ketamine in Chap. 12).

HORSES. The recommended dose of promazine in the horse is 0.44–1.1 mg/kg via the IV or IM route. When 0.88 mg/kg promazine is administered intramuscularly to a horse weighing 454 kg (total dose of 400 mg), the effect of the drug is apparent in 10–15 minutes and lasts about 0.5 hour (Fraser 1967). According to Fraser, promazine takes effect less rapidly than acepromazine.

Promazine is also useful in facilitating dental operations such as "floating the teeth" of horses. In loading and surface transportation of horses, promazine is valuable. Heath (1978) prefers not to give foals phenothiazines because they usually sleep all day before recovery occurs.

Promazine has been recommended for treatment of tetanus in horses. However, side effects of phenothiazines include stimulation of extrapyramidal neuronal pathways. It would seem that these effects of promazine and other phenothiazines would result in their contraindication as therapeutic agents for treatment of tetanus. Many clinicians now favor use of diazepam in treatment of tetanus.

Promazine has also been used as a treatment for equine colic. However, severe arterial hypotension may occur in the presence of devitalized bowel and impending shock.

Promazine is used in conjunction with chloral hydrate and ultrashort-acting barbiturates in the horse. The procedure consists of administering promazine intravenously in a dose of 0.7–1.1 mg/kg. Ten minutes following IV injection, 7% chloral hydrate is administered intravenously at a dose of 333 mL/454 kg. After casting the animal, a catheter is placed in the external jugular vein so that a barbiturate can be injected to maintain surgical anesthesia. Barbiturates should not be used intravenously in the horse without preanesthetic sedation. An IV dose of 0.55 mg/kg promazine is recommended for preanesthesia. Promazine has been used in combination with ketamine for induction of anesthesia in horses (see clinical use of ketamine in Chap. 12).

Promazine is also provided for oral use in the feed. The oral dose is 0.99–1.98 mg/kg. Promazine must not be used in horses intended for human food.

CATTLE. The granular form of promazine can be used in feed of nonlactating cattle (1.65–2.75 mg/kg). In the opinion of Garner et al. (1975), a smoother recovery from general anesthesia occurs when promazine is not used as a preanesthetic agent.

Unless the drug has been withdrawn from feed for at least 72 hours prior to slaughter, animals cannot be sold for human consumption. The established tolerance level for promazine in food is zero.

SWINE. Promazine (2 mg/kg) along with atropine (0.07–0.09 mg/kg) and meperidine hydrochloride (1–2 mg/kg) is useful as a preanesthetic in swine used for experimental surgical purposes (Booth 1969). Promazine provides a mild tranquilizing effect and assists in restraint of the pig prior to general anesthesia.

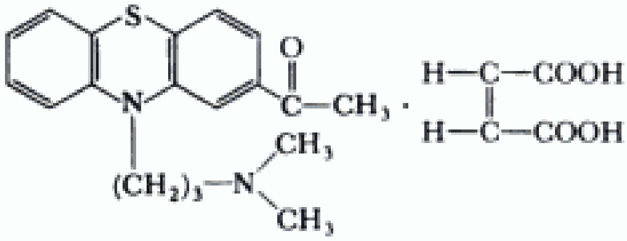
RABBITS. Promazine has been used in combination with ketamine for induction of anesthesia in rabbits (see clinical use of ketamine in Chap. 12).

LABORATORY ANIMALS. A combination of promazine and ketamine has been used in rats and mice for induction of short-term anesthesia (see clinical use of ketamine in Chap. 12).

EXOTIC SPECIES. Promazine has been used in tranquilizing bears. IM injection of 4.4 mg/kg promazine is effective in potentiating morphine. Promazine has been useful in combination with other drugs for immobilization of bears as well as other exotic species (Seal and Erickson 1969).

Preparturient and postparturient use of promazine has been successful in a hippopotamus weighing about 2273 kg (Graham-Jones 1962); 4.4 mg/kg, or a total of 10 g, were used in the feed and administered daily for 1 week prior to parturition, which occurred normally, with survival of the calf.

Acepromazine Maleate. *Acepromazine Maleate*, INN (Atravet, Notensil, Promace), formerly called acetylpromazine, is approved by the FDA for use in the dog, cat, and horse. This phenothiazine derivative is extensively used in veterinary medicine. Acepromazine is 2-acetyl-10-(3-dimethylaminopropyl) phenothiazine (Fig. 14.4). The drug is a yellow, odorless, crystalline powder with a bitter taste; the powder melts at 135–138° C.



Acepromazine Maleate

FIG. 14.4

PHARMACOLOGIC CONSIDERATIONS. Most of the pharmacologic effects of acepromazine are similar to those of other phenothiazine derivatives. It is more potent than chlorpromazine and promazine and is effective parenterally in small doses. The contraindications are generally the same as those for promazine and chlorpromazine.

Experimentally, acepromazine decreases arterial blood pressure in the dog 3 minutes after 1 mg/kg is administered by the IM route (Popovic et al. 1972); this effect lasts 2 hours. A significant increase in central venous pressure occurs 90 minutes after administration of the drug and generally persists for the duration of its effect. Intermittent bradycardia also occurs (Popovic et al. 1972). Sinoatrial (SA) arrest occurs at 3.5 minutes following injection of acepromazine and lasts about 8 seconds; recovery is spontaneous, with no apparent permanent cardiac injury. Atropine (0.045 mg/kg) should be used in conjunction with acepromazine prior to administration of a general anesthetic to minimize or prevent vagal effects that may induce bradycardia or SA arrest. IV acepromazine (0.033 or 0.067 mg/kg) does not induce cardiac arrhythmia in horses anesthetized with halothane (Steffey et al. 1985).

Following IV administration of acepromazine in doses of 0.11, 0.55, and 1.1 mg/kg, decrease in arterial pressure occurs in the dog (Coulter et al. 1981). Interestingly, the decline in pressure was not dose related; the lowest IV dose (0.11 mg/kg) appeared to reduce arterial pressure as markedly as the highest dose (1.1 mg/kg). The results of Coulter et al. are in contrast to those found in the dog by Muir and Hubbell (1985); they found that an IV dose of acepromazine less than 0.4 mg/kg is not likely to produce significant changes in the arterial pressure of healthy dogs.

Doses (0.05, 0.125, and 0.25 mg/kg) of IV acepromazine in the dog decrease the mean arterial pressure from 2.3 ± 6.0 to 16.8 ± 14.2% (Ludders et al. 1983). Phenylephrine, an α-adrenergic agonist, antagonizes the hypotensive action of acepromazine; an IV dose of 0.088 mg/kg (a clinically recommended dose) or higher is necessary to increase the mean arterial pressure. Phenylephrine has a duration of 20 minutes after IV administration.

In the dog, acepromazine blocks or prevents arrhythmic and ventricular fibrillatory actions of epinephrine and halothane (Muir et al. 1975). It markedly decreases respiratory rate in the dog. Despite this, however, no significant alteration results in the P_aCO_2, pH, P_aO_2, and oxyhemoglobin saturation (Popovic et al. 1972). Significant drops in level of hemoglobin concentration are first observed 45 minutes after drug administration; this persists for at least 2 hours.

Administration of acepromazine (0.09 mg/kg) intravenously in the horse induces an insignificant decrease in heart rate and cardiac output when compared with baseline or control values (Muir et al. 1979). Mean pulmonary arterial pressure does not decrease significantly from control values following this dose. However, the mean central venous pressure, mean aortic pressure, and respiratory rate in the horse decrease significantly 15 minutes following injection. Although the respiratory rate is decreased by acepromazine, the arterial pH, P_aO_2, and P_aCO_2 are not significantly different from control values (Muir et al. 1979).

Acepromazine in an extremely low IV dose (0.002 mg/kg) produces a significant effect upon the hematocrit or PCV; this is the most sensitive pharmacologic response induced by acepromazine in the horse (Ballard et al. 1982). This is followed by changes in penile extension and depression of the respiratory rate, which are the next most sensitive responses to acepromazine in the horse.

In general, the effect of acepromazine upon reduction of the hematocrit in the horse is dose dependent. For example, an IV dose as low as 0.01 mg/kg reduces the hematocrit by 25% within 30 minutes after acepromazine administration (Ballard et al. 1982); higher doses may reduce the hematocrit as much as 50%. Duration of the effect upon the hematocrit may be 12 or more hours before the PCV recovers to normal; e.g., mean hematocrit values recover to control levels by 12 hours after IV doses of 0.05 mg/kg and 21 hours after 0.15 mg/kg (Parry and Anderson 1983). The decrease in hematocrit is primarily due to splenic sequestration of red blood cells.

The hypotensive action of acepromazine in the horse is related to both the dose and the route of administration (Parry et al. 1982). In healthy horses, the arterial pressure remains significantly below control values for more than 6 hours after an IM injection of 0.025 mg/kg. According to Parry et al. (1982), individual horses vary in responsiveness to acepromazine. For example, one horse decreased from a resting value of 112/82 to 91/55 mm Hg at 1 hour after IV administration of acepromazine (0.1 mg/kg) and returned to 111/79 mm Hg in 4 hours. In another animal after the same IV dose, the arterial pressure decreased from 132/94 to 61/45 mm Hg at 15 minutes after injection; the pressure remained below 87/67 mm Hg for 6 hours after injection and recovered to normal (125/90 mm Hg) at 15 hours.

In general, greater tranquilization induced by acepromazine results in greater arterial hypotension. Thus acepromazine is a dangerous drug in circumstances where circulatory embarrassment or acute circulatory failure is a possibility (Parry and Anderson 1983).

In treatment of equine colic, an adequate blood volume and arterial pressure are necessary before acepromazine or related derivatives can be safely used; most fatal colic cases are probably due to cardiovascular collapse. Considering the marked arterial hypotension and prolonged effect of acepromazine in healthy horses and the speed with which hypotension can occur in colic cases, use of acepromazine or other phenothiazines at any stage in treatment of equine colic is seriously questioned (Parry and Anderson 1983).

Arterial hypotension after administration of acepromazine also occurs in the healthy cat. When administered intramuscularly at 0.11 mg/kg, the arterial pressure declines 30% within the first 10 minutes postinjection (Colby and Sanford 1981). Acepromazine in combination with ketamine induces a shorter depressant effect upon the mean arterial pressure, heart, and respiratory rates than ketamine-xylazine combinations (Sanford and Colby 1982).

After IV injection, acepromazine is distributed extensively in the horse (Vd = 6.6 L/kg) and binds extensively (>99%) to plasma proteins (Ballard et al. 1982). Plasma concentrations of acepromazine (after an IV injection of 0.3 mg/kg) decline with an α-phase half-life of 4.2 minutes; the β-phase, or elimination, half-life is about 185 minutes.

Acepromazine in IM doses of 1.1 and 1.65 mg/kg respectively prevents occurrence of halothane-induced malignant hyperthermia in 40 and 73% of susceptible pigs (McGrath et al. 1981). For additional information on halothane-induced malignant hyperthermia, see Chap. 11.

Following IM administration of acepromazine (0.01–0.1 mg/kg) in mature Standardbred mares, metabolites are present in urine (Maylin 1978). The metabolites are 2-(1-hydroxyethyl) promazine sulfoxide, 2-(1-hydroxyethyl) promazine, 7-hydroxyacetylpromazine, and 2-(1-hydroxyethyl)-7-hydroxypromazine.

CONTRAINDICATIONS AND PRECAUTIONS. Clinically, a few case reports have revealed adverse reactions following administration of acepromazine in dogs (Garland and White 1968; White 1968). Within 5–10 minutes after IM injection of 0.55 mg/kg acepromazine, sudden collapse has been observed. Initially, animals manifested apnea, then a slow pulse and unconsciousness. A fatal interaction involving Diathal, thiamylal, and acepromazine has been reported in the dog (Webb et al. 1983). See discussion under the toxicity of thiamylal in Chap. 12 of the 7th edition of this text. Adverse behavioral alterations have been observed in use of acepromazine in the dog; aggressiveness and vicious behavior are sometimes manifested after administration (Waechter 1982).

According to Dodman et al. (1984), acepromazine can produce complications in certain conditions: (1) In most types of shock, use of acepromazine in low cardiac output states or hypervolemia can result in a critical drop in arterial pressure and venous return owing to its α-adrenergic blocking action. (2) CNS seizure threshold may be lowered by acepromazine, which can trigger seizures in susceptible animals. It should not be

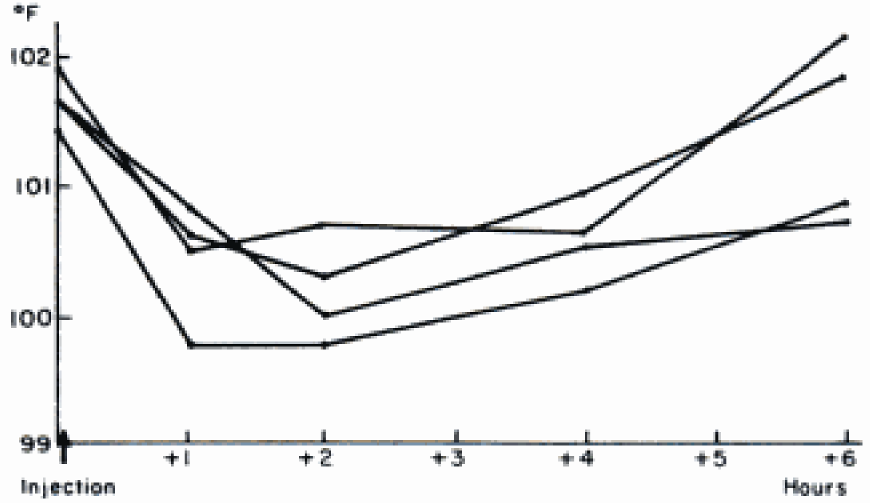


FIG. 14.5.—Changes in rectal temperature of four dogs following IM injection of acepromazine at a dose of 0.25 mg/kg (Pugh 1964).

used in these animals or animals undergoing myelographic procedures. (3) Acepromazine can cause syncope associated with high vagal tone and subsequent bradycardia; this occurs in brachycephalic breeds, particularly in Boxers. The response may be prevented by administering a low dose of acepromazine and a concomitant injection of an anticholinergic agent such as atropine.

Caution in administration of acepromazine to weak, debilitated, aged, and cardiac disease patients must be observed to minimize adverse effects. Also, a drug interaction with organophosphates must be avoided because toxicity of the phenothiazines is enhanced. Mixing glycopyrrolate in the same syringe with phenothiazines or diazepam is contraindicated (Short et al. 1984).

CLINICAL USE. The primary use of acepromazine has been as a preanesthetic agent in the dog, cat, and horse. It markedly potentiates barbiturates and facilitates handling and restraint of animals.

DOGS. Acepromazine may be administered by the IV, IM, SC, or oral route in the dog. For preanesthetic use, the IM dose (0.05–0.1 mg/kg) is considerably lower than that used for ordinary restraint purposes (Dodman et al. 1984) (see below). The recommended dose of acepromazine for the parenteral routes ranges from 0.55 to 1.1 mg/kg; for oral administration in tablet form, the recommended dose is 0.55–2.2 mg/kg. All doses may be repeated, depending on degree and duration of tranquilization required. Usually it is necessary to repeat the dose every 6–8 hours to maintain tranquilization. Because of the potent effect of acepromazine, most clinicians generally use dosages below those recommended above in the dog. Since there is individual variation in the responses induced by acepromazine, it is best to begin on the conservative side in dose administration. If necessary, more drug can always be given later.

According to Pugh (1964), oral administration of 1–3 mg/kg acepromazine in a single dose produces deep sedation in the dog. This is also accompanied by lethargy and reduced motor activity as evidenced by some posterior ataxia. Onset of the effect is noted by changes in facial expression. Skin overlying the frontal portion of the skull appears more pliable and wrinkled, the upper eyelid droops (ptosis), and the nictitating membrane is relaxed and protruded. The first indication of posterior ataxia is usually evident at this time. Recumbency soon follows, and the animal frequently goes into a somnolent state.

Clinical signs of acepromazine usually begin to regress after 3–4 hours but may be present after 7 hours (Pugh 1964). As in other species, a drop in rectal temperature occurs. This effect is shown in Fig. 14.5.

For preanesthetic use, the dose of acepromazine is 0.11 mg/kg intramuscularly (Rosin 1974). Also, atropine (0.045–0.066 mg/kg) is administered by the IM or SC route. After the peak effect (usually 15–20 minutes) of acepromazine has been attained, thiamylal is then administered to effect to produce general anesthesia; this permits endotracheal intubation so that inhalant anesthetics may be administered. The dose of thiamylal necessary to produce general anesthesia is reduced by about 50%. Like other phenothiazines (chlorpromazine, promazine), acepromazine produces a moderate degree of blockade of the α-adrenergic receptors. This effect is believed to assist in prevention of renal ischemia and maintenance of adequate kidney function during general anesthesia as well as in minimization of postsurgical uremia (Rosin 1974).

Adequate sedation is provided by 0.04 mg/kg acepromazine in the dog prior to induction with thiamylal; the route of administration was not specified (Rutherford 1983). It was probably given intramuscularly.

According to Rutherford, no more than a total of 3 mg acepromazine is given to any dog, and large dogs may be sensitive to a total of 2 mg.

Acepromazine in a large IM dose (0.3 mg/kg) has been used in dogs 20 minutes prior to euthanasia with carbon monoxide (Dallaire and Chalifoux 1985). It improves the esthetic aspects of the use of carbon monoxide in euthanasia by decreasing vocalization, agitation, and other effects in the dog.

An IV combination of acepromazine (0.2 mg/kg) and ketamine (10 mg/kg) is useful for clinical anesthesia in the dog if stimulation of cardiovascular function is not necessary or desirable (Farver et al. 1986; see clinical uses of ketamine in Chap. 12). This combination probably should not be used in dogs predisposed to arterial hypotension or respiratory depression.

For neuroleptanalgesic purposes, acepromazine (0.11 mg/kg) has been administered (route of administration unspecified, probably IM) in combination with oxymorphone (0.2 mg/kg). This permits intubation and use of halothane-oxygen for induction of anesthesia (Short et al. 1984).

Acepromazine (0.1 mg/kg) is recommended for antiemetic use in the dog. The route of administration was not specified by Willard (1985); it was probably by the IM or IV route to be effective immediately. This dose of acepromazine is ineffective in preventing apomorphine-induced emesis. An IM dose of 0.5 mg/kg does not block the emetic action of an IV dose of 0.04 mg/kg apomorphine in dogs (Keith et al. 1981).

Acepromazine in large doses has been recommended for treatment of metaldehyde poisoning in the dog. However, diazepam is preferable for control of convulsive seizures induced by metaldehyde. A side effect of phenothiazine neuroleptics, including acepromazine, is stimulation of extrapyramidal motor pathways. Thus acepromazine would lower the convulsive threshold and is not the drug of choice for treatment of metaldehyde toxicity.

CATS. Acepromazine may be administered by the IV, IM, SC, or oral route in the cat. The recommended dose for the parenteral and oral routes ranges from 1.1 to 2.2 mg/kg. It is usually necessary to repeat the dose every 8–12 hours to maintain tranquilization. Many of the drug effects produced in the dog are also seen in the cat (see above). Since acepromazine is a potent phenothiazine derivative, most clinicians generally use dosages below those recommended in the cat. It is best to begin on the conservative side of dose administration. Larger doses can always be given later to produce the desired effect.

Clinically, acepromazine is important as a preanesthetic agent in the cat. The dose successfully used in clinical practice is 0.11 mg/kg administered intramuscularly (Rosin 1974). Atropine (0.045–0.066 mg/kg) is also injected intramuscularly or subcutaneously. General anesthesia with an ultrashort-acting barbiturate or inhalant anesthetic may be administered 15–20 minutes after the peak effect of acepromazine has been reached. As in the dog, the amount of general anesthetic is reduced significantly.

IV acepromazine (0.11 mg/kg) has been used in the cat with IV ketamine (11 mg/kg) to provide skeletal muscle relaxation and a smoother recovery (Wright 1982). However, in a double-blind study, acepromazine did nothing to contribute to the effect of ketamine in the cat; according to Chase (1977), piperacetazine hydrochloride is more useful.

HORSES. Acepromazine must not be used in horses intended for human consumption. It may be administered intravenously or intramuscularly. The recommended preanesthetic dose ranges from 0.02 to 0.05 mg/kg.

Because of the potent effect of acepromazine, most clinicians use dosages below those specified by manufacturers. MacKenzie and Snow (1977) noted that the tranquilizing action of acepromazine may last for 24 hours in the horse; this is considerably longer than the responses (i.e., 8 hours) claimed by the manufacturers' recommended dosages.

According to Fraser (1967), acepromazine administered at an IM dose of 0.066 mg/kg is effective in 2–3 minutes. Clinical signs are drooping of the upper eyelid, slight protrusion of the nictitating membrane, and dropping of the head below its normal level. An overdose of the drug produces ataxia and may interfere with clinical procedures.

Acepromazine reduces excitability so that the animal can be easily handled; e.g., rectal examination and exploration of the genitalia are facilitated. Some clinicians have dispensed oral acepromazine tablets to provide tranquilization of horses for travel in a trailer. The dose for this purpose is 2–4 mg/45 kg; tablets of the drug are generally buried in a piece of apple and administered 30–45 minutes prior to loading.

Tranquilization of dangerous animals may lead to a false sense of security. Painful procedures should be avoided because phenothiazines provide little, if any, analgesic effect.

Horses medicated with acepromazine retain auditory and visual acuity; loud sounds or rapid movements should be avoided.

Acepromazine even in high therapeutic doses infrequently produces recumbency. Although horses may appear to be somnolent, they will usually remain standing. In the event the animal lies down, it can ordinarily be persuaded to stand. Risk of the animal stepping or falling on the attending veterinarian is minimal. Retention of coordination and alertness in the horse is important, since many diagnostic and surgical procedures must be conducted upon a standing animal (Ballard et al. 1982).

An important use of acepromazine is as a preanesthetic. A total dose of 15 mg/454 kg, or 0.033 mg/kg, is administered intravenously and followed 10 minutes later with an IV injection of thiamylal (2.5–3 g/454 kg) (Shideler 1971). This permits endotracheal intubation so that an inhalant anesthetic can be administered for maintenance of surgical anesthesia.

Acepromazine is being used in treatment of equine colic. An IV dose of 0.066 mg/kg brings about prompt relief (Frank 1970). This effect is due to its antispasmodic activity. Partial blockade of the α-adrenergic receptors may possibly explain this antispasmodic effect. Adequate blood volume and arterial pressure are necessary before acepromazine or related derivatives can be used safely; most fatal colic cases are probably due to cardiovascular collapse or shock. Considering the marked arterial hypotensive effect of acepromazine in healthy horses and the rapidity with which hypotension can occur in colic cases, use of acepromazine at any stage in treatment of equine colic is seriously questioned (Parry and Anderson 1983).

Acepromazine in combination with meperidine, an analgesic and antispasmodic drug, is considered to be an effective neuroleptanalgesic agent in the horse (Jones 1972). The IV dose of the mixture is 100 mg acepromazine and 50 mg meperidine for animals weighing 454 kg; nervous and highly bred or excited animals receive a higher dose; calm, less excitable animals receive less of the mixture (Schauffler 1968). Since these agents may induce severe arterial hypotension, extreme caution is necessary in their use. This is particularly true in the presence of shock.

Acepromazine-methadone in combination with ketamine has been used in the horse. For detailed information on this combination of drugs, see the discussion on methadone in Chap. 13.

A combination of acepromazine and another analgesic agent (etorphine hydrochloride) has been advocated in the horse and other domestic animals in the UK (see Chap. 13). Acepromazine in a concentration of 10 mg/mL is combined with 2.45 mg/mL etorphine; this neuroleptanalgesic preparation is sometimes used for minor surgery (Jenkins 1972).

Priapism or penile prolapse occurs occasionally following use of phenothiazine neuroleptic agents; acepromazine is associated with this condition in the horse (Pearson and Weaver 1978). IV doses (0.04 and 0.1 mg/kg) induce essentially complete penile protrusion within 30 minutes after administration; at the higher dose, protrusion remains maximally distended up to about 100 minutes following administration (Tobin and Ballard 1979). The duration and extent of penile protrusion are dose related; a dose of acepromazine as low as 0.01 mg/kg induces penile prolapse (Ballard et al. 1982). At 0.4 mg/kg, prolapse occurs for 4 hours and does not retract completely until 10 hours after administration of acepromazine. Acepromazine-induced prolapse of the penis in a 3-year-old Thoroughbred gelding was corrected by a slow IV injection of 8 mg *Benztropine Mesylate*, USP (Cogentin); within 30 minutes after administration, the penis appeared normal, flaccid, and retracted (Sharrock 1982). According to Sharrock, it may be necessary to increase or repeat the benztropine dose in stallions.

Penile prolapse may in part be due to relaxation of retractor penis muscles, which are innervated by adrenergic nerve fibers. Relaxation may occur from the α-adrenergic blocking effects of acepromazine. Etorphine in combination with acepromazine may also contribute to the development of priapism. Of 7 horses with priapism following use of acepromazine, 5 had also received etorphine in combination with the phenothiazine neuroleptic agent (Pearson and Weaver 1978). Inasmuch as the penis is prolapsed and turgid following the sole use of etorphine and is flaccid following the use of only acepromazine, elevated blood pressure induced by etorphine has been suspected to be a contributory factor leading to penile paralysis. However, it is highly improbable that etorphine would increase the arterial pressure high enough to induce paralysis. During coitus the pressure generated in the corpus cavernosum penis is several thousand mm Hg and that in the corpus spongiosum penis is usually greater than 700 mm Hg (Beckett et al. 1973, 1975). With administration of acepromazine and etorphine in a combined mixture, arterial pressure does not increase; instead it may become dangerously hypotensive. Thus priapism still occurs following hypotension induced by the drug mixture. Consequently, an elevated arterial pressure seen with use of etorphine alone would not appear to be a contributory factor in development of priapism. Since difficulties are encountered with use of acepromazine in stallions, the drug should not be used in stud or breeding animals.

CATTLE. Acepromazine has not been approved by the FDA in food-producing animals because of the potential risk of residues in meat and milk products.

In the opinion of Garner et al. (1975), a smoother recovery from general anesthesia in cattle occurs when acepromazine is not used as a preanesthetic agent. A sedative dose (0.05–0.01 mg/kg) of acepromazine has been used in cattle by the IV, IM, or SC route (Howard 1981). According to Hubbell et al. (1986), acepromazine in an IV dose of 0.01–0.02 mg/kg or an IM dose of 0.03–0.1 mg/kg produces mild sedation. It is useful for calming nervous cattle when used in conjunction with local anesthesia for surgical procedures. It fails to induce sufficient sedation in control of unmanageable or hyperexcited cattle. Arterial blood pressure may be decreased severely after use of acepromazine in sick or debilitated cattle. Acepromazine is not recommended as a preanesthetic in calm cattle, and it may have little effect in cattle that do not tolerate restraint (Hubbell et al. 1986).

Caution in use of acepromazine in cattle is advised; more data are needed to determine its safety and efficacy. Death has occurred in cattle injected with acepromazine after prolonged transit. Transit under stressful conditions (in cold or hot weather, without water or feed, for long distances) increases the susceptibility and risk of animals to the arterial hypotensive action of acepromazine.

SWINE. For tranquilization or sedation, Anderson (1973) recommends IV administration of 0.03–0.1 mg/kg. As a preanesthetic agent, Benson and Thurmon

(1979) use acepromazine intramuscularly in a dose of 0.11–0.22 mg/kg; they do not recommend a total dose of more than 15 mg in any pig. According to McGrath (1984), IM morphine (1–2 mg/kg) in combination with IM acepromazine (0.05–0.2 mg/kg) can be substituted for the combination of fentanyl-droperidol (Innovar-Vet) in depressed or toxemic sows.

Acepromazine is also used in combination with ketamine for induction of anesthesia in miniature swine (see clinical uses of ketamine in Chap. 12).

SHEEP AND GOATS. Acepromazine (0.05–0.1 mg/kg) has been used in conjunction with ketamine (2–5 mg/kg) by the IM or IV route (McGrath 1984). For more information on use of these drugs in combination, see Chap. 12.

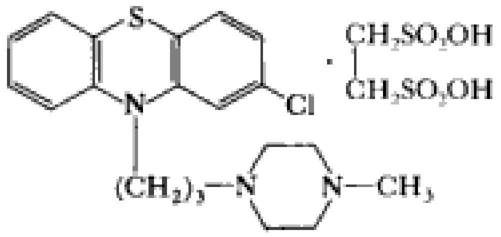
RABBITS. Acepromazine administered intramuscularly at 1 mg/kg will tranquilize the rabbit in about 10 minutes for 1–2 hours (Wood 1978).

Prochlorperazine Edisylate. *Prochlorperazine Edisylate,* USP (Darbazine, Compazine), is a piperazine derivative of phenothiazine (Fig. 14.6). Extrapyramidal symptoms, especially at high dosages, are more characteristic of piperazines than of nonpiperazine derivatives (e.g., chlorpromazine, promazine, acepromazine). The antiemetic properties of piperazine phenothiazine derivatives are greater than those of nonpiperazine derivatives.

Pharmacologically, the sedative effect of prochlorperazine is moderate compared to chlorpromazine and triflupromazine hydrochloride. Consequently, only a slight effect upon consciousness is elicited by prochlorperazine. The hypotensive and respiratory effects are low compared to promazine.

Prochlorperazine has been approved as an injectable preparation by the FDA for use in combination with isopropamide iodide, which is a potent, long-acting anticholinergic drug that suppresses both gastrointestinal (GI) motility and secretions for about 12 hours after a single oral dose. This injectable combination has been approved for use in the dog and cat.

PRECAUTIONS AND CONTRAINDICATIONS. Precautions and contraindications previously described for the phenothiazine neuroleptic agents are essentially similar for prochlorperazine. It is contraindicated in cases of glaucoma, stenosis or obstruction of the pylorus, and prostatic hypertrophy. Since extrapyramidal effects are marked following use of prochlorperazine, caution should be used in administering this drug to animals subject to convulsive disorders. Capsules (Neo-Darbazine) that contain neomycin must not be used in dogs that have renal disorders.



Prochlorperazine Edisylate

FIG. 14.6

CLINICAL USE. In the dog (but not the cat) a sustained-release capsule for oral use has been approved by the FDA. The capsule contains prochlorperazine dimaleate and isopropamide to provide control of GI disturbances associated with emotional stress.

The injectable preparation contains 6 mg/mL of prochlorperazine edisylate or the equivalent of 4 mg prochlorperazine and 0.38 mg/mL isopropamide iodide or the equivalent of 0.28 mg isopropamide. The drug combination in the dog and cat is based on SC injection twice daily at a dosage as follows (Code of Federal Regulations 1974):

Animal weight (kg)	*Dose (mL)*
Up to 1.8	0.25
2.2–6.8	0.5–1
6.8–13.6	2–3
13.6–20.4	3–4
20.4–27.2	4–5
Over 27.2	6

If medication needs to be continued in the dog, a change to the oral form or sustained-release capsules can be made in 6–8 hours following the last injection. Two capsule sizes are available for dogs, the small size for animals weighing up to 13.6 kg and the large size for dogs weighing 13.6 kg and over. The small capsules contain 3.33 mg prochlorperazine dimaleate and 1.67 mg isopropamide; the dose is administered by the oral route twice daily as follows: less than 1 capsule or fraction thereof for animals weighing less than 1.8 kg, 1 capsule/1.8–6.8 kg, and 1–2 capsules/6.8–13.6 kg. The large capsules contain 10 mg prochlorperazine dimaleate and 5 mg isopropamide; the dose is administered by the oral route twice daily as follows: 1 capsule for animals weighing 13.6 kg and over.

Prochlorperazine and isopropamide have also been combined with neomycin sulfate to provide a product (Neo-Darbazine) for treatment of infectious enteritis in the dog. It is particularly indicated in cases of emotional stress that are associated with bacterial infections. In the small capsule, 35.7 mg/kg neomycin sulfate is added, which is equivalent to 25 mg neomycin base. Identical quantities of prochlorperazine and isopropamide are present in the small sustained-release capsule as described above. In the large capsule, 107 mg neomycin sulfate or the equivalent of 75 mg neomycin base is added; again, identical quantities of prochlorperazine and isopropamide are present in the large sustained-release capsule as described above. Each large capsule is equivalent to three small capsules in content.

The twice-daily oral dose schedule of the small, 25 mg neomycin-base capsule is as follows:

Animal weight (kg)	*No. of small capsules*
4.5–9	1
9–13.6	2
Over 13.6	3

The twice-daily oral dose schedule of the large, 75 mg neomycin-base capsule is as follows:

Animal weight (kg)	*No. of large capsules*
Over 13.6	1
Over 27	2

Medication should not last for more than 5 days. Most cases will respond favorably within this time. If not, the diagnosis and/or therapy must be reconsidered.

Prochlorperazine edisylate (1 mg/kg) without isopropamide has been suggested in the dog for antiemetic effects (Willard 1985). Administration was not specified; it was probably given by the SC or IM route.

Trimeprazine Tartrate. *Trimeprazine Tartrate,* USP (Temaril), chemically is (*dl*-10-[3-dimethylamino-2-methylpropyl]-phenothiazine) (Fig. 14.7). In addition to having a tranquilizing effect, it is antipruritic, antitussive, and antihistaminic.

Trimeprazine (5 mg) is combined with prednisolone (2 mg) in tablet form for oral administration in the dog, which is the only species in which this combination product (Temaril-P) has been approved by the FDA. Twice-daily oral doses are as follows:

Weight (kg)	*Tablets*
Up to 4.5	0.5
5–9	1.0
9.5–18	2.0
Over 18	3.0

Following 4 days of treatment, the dose is decreased to about one-half the initial dose, which is sufficient to prevent return of symptoms. Because of individual variation, doses will need to be regulated in accordance with the clinical response desired.

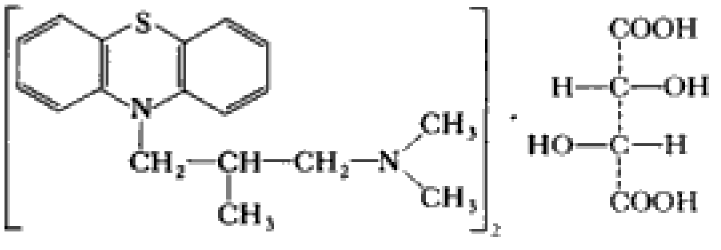
Trimeprazine-prednisolone is indicated for alleviation of pruritis, irrespective of etiology, and for reduction of inflammatory reactions associated with skin disorders such as eczema, otitis, and allergic dermatitis. The drug combination has been advocated as an adjunctive treatment in conditions such as kennel cough and various forms of bronchitis. Thus this product also has antitussive activity.

With incorporation of prednisolone into the tablet, the preparation must not be used in viral infections or ulceration of the cornea. Healing of the cornea will be delayed or inhibited. Moreover, prednisolone should not be used in the last trimester of pregnancy because it may induce premature parturition with dystocia, fetal death, retained placenta, and metritis.

α_2-ADRENERGIC AGONISTS

The α_2 Adrenoceptor. Alpha$_2$-adrenergic agonists have been used by veterinarians for over two decades to provide dose-dependent sedation, analgesia, and muscle relaxation. Xylazine was synthesized in Germany in 1962 and was the first α_2-adrenergic agonist to be used as a sedative and analgesic by veterinarians. Reports on the effectiveness of xylazine as an anesthetic adjunct began to appear in the 1970s, but it was not until 1981 that xylazine's anesthetic action was linked to the stimulation of central α_2-adrenergic receptors (adrenoceptors) (Hsu 1981; Clough and Hutton 1981). Alpha$_2$ adrenoceptors have been identified in the cardiovascular, respiratory, renal, endocrine, gastrointestinal, hematologic, and central nervous systems.

α adrenoceptors were originally classified into α_1 and α_2 subtypes based on the pharmacologic effects of yohimbine and prazosin (Cheung et al. 1982). The α_2-adrenoceptor belongs to the group of membrane receptors known as G-protein-coupled receptors (Gilman 1987). Transduction of a message carried by an α_2 agonist into cellular responses is referred to as transmembrane signaling and involves the coupling of at least three components: a receptor protein, a guanine nucleotide-binding regulatory protein (G protein), and an effector mechanism. When an α_2 agonist binds to the receptor, a conformational change occurs that facilitates contact with the G protein. The G proteins allow rapid stimulation of an effector system. Effector mechanisms are most often changes in transmembrane voltage and neuronal excitability. At least five separate



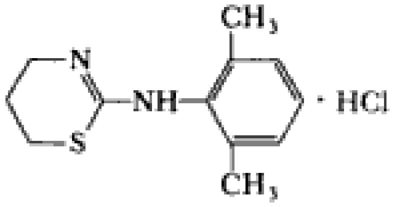
Trimeprazine Tartrate

FIG. 14.7

effector mechanisms that are directly modulated by the activated α_2 adrenoceptor have been identified (Maze and Tranquilli 1991). For example, the reduction in anesthetic requirement demonstrated by the superselective α_2 agonist dexmedetomidine is probably mediated by a central α_2-adrenergic isoreceptor and involves a pertussis toxin–sensitive G protein and a 4-aminopyridine-sensitive potassium channel (Doze et al. 1989; Regan et al. 1989; Doze et al. 1990). Similarly, a pertussis toxin–sensitive G protein and a voltage-operated calcium channel appear to be involved in the analgesic response to an α_2 agonist (Hoehn et al. 1988; Dunlap and Fischbach 1981; Holz et al. 1986). Enhancement of the analgesic response may also occur as the result of a synergistic interaction between α_2-adrenergic agonists and opiates in the spinal cord (Ossipov et al. 1989; Drasner and Fields 1988).

The adrenoceptor has been described structurally as seven hydrophobic transmembranous domains consisting of 20–25 amino acids in an α-helical configuration. The hydrophobic domains are believed to determine the specificity of ligand recognition by forming binding sites for small ligands. The seven hydrophobic domains are separated by three intracellular and three extracellular loops of variable lengths comprising hydrophilic amino acids. The intracellular loops provide the site of interaction with G proteins.

Efforts are presently being directed toward classification of α_2-adrenoceptor subtypes (Aantaa et al. 1995; Kendall 1996; MacKinnon et al. 1994; Bylund 1988). Pharmacologic studies utilizing selective antagonists have identified four α_2-adrenoceptor subtypes: α_{2A}, α_{2B}, α_{2C}, and α_{2D}, although it has been suggested that the α_{2D} subtype may actually be a species homolog of the α_{2A} subtype. Although amino acid sequencing and chromosomal location support the existence of α_2-adrenoceptor subtypes, the functional significance, if any, of the α_2-adrenoceptor subtypes remains to be determined.



Xylazine Hydrochloride

FIG. 14.8

Xylazine Hydrochloride. *Xylazine Hydrochloride*, INN (Rompun, Bay Va 1470), was first synthesized in 1962 and given the code name Bay Va 1470. Chemically, xylazine is 2(2,6-dimethylphenylamino)-4*H*-5,6-dihydro-1,3-thiazine hydrochloride (Fig. 14.8); it is related to clonidine, a drug used to control arterial hypertension in humans. Pharmacologically, xylazine is classified as an analgesic as well as a sedative and skeletal muscle relaxant. It is not a neuroleptic or tranquilizer nor an anesthetic agent. Xylazine is approved by the FDA for use in the dog, cat, horse, deer, and elk.

PHARMACOLOGIC CONSIDERATIONS. Xylazine is a potent α_2-adrenergic agonist. It acts upon the CNS by activation or stimulation of α adrenoceptors such as the α_2-adrenergic receptors; this decreases sympathetic discharge and reduces release of norepinephrine. Receptors that control central neuronal dopamine and norepinephrine storage and/or release are α_2 adrenoceptors (Hedler et al. 1981). Through its central stimulation of α_2-adrenegic receptors, xylazine has potent antinociceptive or analgesic activity. In addition to α_2-adrenergic activity, xylazine has α_1-adrenergic effects (Kobinger and Pichler 1982). Consequently, xylazine elicits both peripheral and central actions upon these adrenergic receptor subtypes.

Xylazine has a number of pharmacologic characteristics in common with morphine, but it will not substitute for morphine in dependent rats, and its effect is not antagonized by naloxone. Xylazine does not produce the CNS excitation usually induced by narcotic analgesics in mice, rats, and cats. Instead, it produces depression and sedation in these species.

Electroencephalographic studies in rabbits and cats suggest that xylazine activates central α adrenoceptors related but distinct from the peripheral α adrenoceptors (Loc et al. 1974). The antinociceptive action is antagonized effectively by yohimbine and piperoxan. Inasmuch as yohimbine has been classified as a specific α_2-adrenoceptor blocking agent upon presynaptic receptors, xylazine apparently induces its major effect at this target site.

Xylazine also produces skeletal muscle relaxation by inhibition of intraneuronal transmission of impulses at the central level of the CNS. Apparently because of direct stimulatory effect upon the emetic center, emesis is commonly induced by xylazine in the cat and occasionally in the dog. The chemoreceptor trigger zone of the area postrema is activated by xylazine to trigger emesis; its action may be mediated by an opiate type of molecular receptor (Colby et al. 1981). Alpha-adrenergic and dopaminergic blocking agents do not prevent xylazine-induced emesis. In contrast to the dog and cat, xylazine does not elicit emesis in cattle, sheep, goats, horses, and some other species.

Xylazine has a variable effect upon the cardiovascular system. In many species, IM or IV injections produce a short-lived arterial pressor effect followed by a longer period of hypotension and bradycardia. These contrasting actions upon the arterial pressure apparently are related to the α_1- and α_2-adrenergic actions of xylazine. For example, the peripheral α_1- and α_2-adrenergic actions of IV xylazine produce an acute arterial vasopressor effect in halothane-anesthetized dogs (Tranquilli et al. 1984). The longer period of arterial hypotension associated with xylazine appears to be related to its central α_2-adrenergic action or decrease in central sympathetic nervous system activity (Schmitt et al. 1970).

Since xylazine can induce arterial hypotension, it is logical to think that this effect would interact with other compounds that induce hypotension, such as acepromazine. According to Muir et al. (1979b), the combination of xylazine and acepromazine is a hemodynamically stable drug mixture in the horse. However, in animals with cardiopulmonary problems, considerable caution should be taken in use of this drug mixture.

Arterial hypotension may result from a depressant effect of xylazine upon cardiac contractility and an associated drop in cardiac output. In dogs given xylazine 20 minutes prior to anesthesia, ventricular arrhythmias, including ventricular fibrillation, are induced with much smaller doses of epinephrine than in nonpremedicated dogs (Muir et al. 1975). Thus xylazine appears to sensitize the heart to epinephrine. Tranquilli et al. (1986) indicate that xylazine does indeed significantly decrease the arrhythmogenic dose of epinephrine in halothane-anesthetized dogs. Recent work, however, suggests that this does not occur when administered in low preanesthetic doses (Lemke et al. 1992).

Cardiac output is decreased 5–10 minutes following IV injection of xylazine (0.66 mg/kg) in the pony and then returns to normal in 15 minutes (Garner et al. 1971a). No significant alteration in the systemic arterial pressure and cardiac rate occurs 2 minutes after administration in the pony. In the horse, atrioventricular (AV) nodal block of the second-degree type occurs (McCashin and Gabel 1975). Additionally, xylazine may induce first- and third-degree AV block in the horse; incomplete AV block generally occurs within 2 minutes of the beginning of IV injection and spontaneously disappears by 4 minutes after IV injection of xylazine (Tranquilli et al. 1984).

A transient second-degree AV block is induced by xylazine in the horse with IV doses of 0.55, 1.1, and 2.2 mg/kg (Kerr et al. 1972b). Atropine sulfate (0.011 mg or more/kg) administered intravenously and immediately before administration of xylazine prevents the heart block. In a clinical evaluation of xylazine in the horse, no cardiac alterations other than bradycardia were reported (Hoffman 1974). It is well known that horses have functional or second-degree heart block, especially young animals. Its incidence may be as high as 16%, and it is not considered a pathologic entity because it disappears following excitement and administration of atropine.

In the horse, bradycardia and second-degree AV block probably occur from increased vagal activity caused by the vasopressor effect of xylazine (Knight 1980). The systolic and diastolic pressures increase initially following IM injection of xylazine (2.2 mg/kg); bradycardia and a decrease in respiration occur. Additionally, the marked depressant effect of thiamylal sodium and halothane following xylazine administration is also obvious (see Fig. 14.9). General anesthetics must be cautiously administered and monitored following use of xylazine.

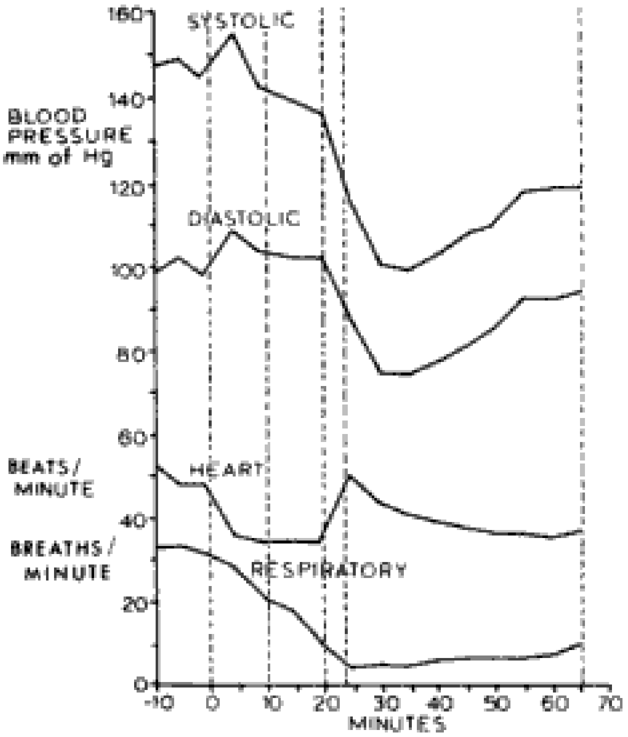


FIG. 14.9.—Mean blood pressure and heart and respiratory rates (determinations on 11 horses). Xylazine was injected at "0" time, thiamylal was injected at 20 minutes, and halothane inhalation was done from 23 to 65 minutes (McCashin and Gabel 1975).

In the dog, IV administration of xylazine (1.1 mg/kg) decreases heart rate and aortic blood flow; there is an initial increase in arterial pressure and peripheral resistance (Klide et al. 1975). Increase in arterial pressure is transient and is followed by decrease in pressure. Additionally, arterial pH, P_aO_2, and P_aCO_2 do not change from control values following this dose of xylazine in the dog (Klide et al. 1975).

IV injection of nifedipine (20 μg/kg), a slow-channel calcium-blocking agent, blocks the initial pressor action of IV xylazine (1.1 mg/kg) in the dog anesthetized with halothane; in addition to blockade of xylazine-induced acute vasoconstriction mediated by α_2-adrenergic receptors, nifedipine blocks the Ca^{++}-dependent action of xylazine but not its α_1-adrenergic receptor action. Also, sinus tachycardia and/or second-degree AV block induced by xylazine are blocked by nifedipine.

Cardiopulmonary effects of the combination xylazine-morphine have been evaluated in the horse (Muir et al. 1979a). In animals given xylazine (0.66 mg/kg) and morphine (0.12 or 0.66 mg/kg) intravenously, a decrease in heart rate, cardiac output, and respiratory rate occurs. Central venous, systemic arterial, and pulmonary arterial pressures also increase. Arterial P_aCO_2 and P_aO_2 as well as arterial pH remain unaltered following administration of the xylazine-morphine combination.

In the pony, no statistically significant alterations occur in arterial pH, P_aCO_2, or P_aO_2 following IV injection of xylazine (0.6–1 mg/kg); no significant change occurs in tidal and minute volumes at this dosage (Garner et al. 1971b).

There is little alteration in serum electrolytes following IV administration of xylazine (1.1 mg/kg) in the horse (Short et al. 1972). Electrolyte values are affected only by a decline in the potassium level. Serum protein levels remain unchanged.

In the horse, the visceral analgesic effects of xylazine were compared with butorphanol, meperidine, and pentazocine (Muir and Robertson 1985). Visceral pain (colic) was produced by inflation of a balloon in the cecum. Of the analgesics studied, xylazine induced the best analgesia. Moreover, the xylazine-induced analgesia was longest (about 90 minutes), followed by butorphanol (about 60 minutes) and then by meperidine and pentazocine (about 30–35 minutes). Similar results have been reported on the analgesic action of xylazine in ponies; obtundation of superficial and visceral pain by xylazine persisted 3 and 4 hours, respectively (Kalpravidh et al. 1984).

In cattle, urine volume or output is greatly increased for about 5 hours following administration of xylazine (Thurmon et al. 1978). Urine pH decreases in cattle during the first hour following administration and then increases. Glucose is detected in bovine urine of xylazine-treated animals 15–30 minutes after injection; it reaches a maximum in 2 hours and is undetectable at 5–6 hours. Additionally, plasma insulin concentrations decrease 25–33% in cattle that receive xylazine by the IM or IV route (Symonds and Mallinson 1978). Administration of insulin 20 minutes after injection of xylazine induces a rapid drop in blood glucose and reduces the rate of glucose production by the liver.

Ruminants are the most sensitive of the domestic animals to the action of xylazine. In cattle, doses that produce deep sedation and analgesia are one-tenth those required in horses, dogs, and cats (Hopkins 1972). Bradycardia and salivation are lessened or prevented in cattle by giving IM atropine (0.1 mg/kg) 10 minutes prior to injection of xylazine (Brown 1986).

In the young Hereford calf, hemodynamic effects of xylazine (0.22 mg/100 kg) administered intramuscularly are quite similar to those observed in other species in both anesthetized and unanesthetized states (Campbell et al. 1979). Effects include bradycardia and decline in the cardiac output and stroke volume as well as increased total peripheral resistance. In other species (but not in the calf) xylazine initially increases mean arterial pressure. Arterial pressure of the calf is markedly lower at 4 minutes after administration than that of control animals (Campbell et al. 1979). In the goat, IM administration of xylazine (0.22 mg/kg) results in significant reduction in respiratory rate (Kumar and Thurmon 1979). The mean arterial blood pressure and rectal temperature remain unaltered.

The pig is less affected than any of these species, and dose levels are reported to be 20–30 times greater than those required in cattle. According to Benson and Thurmon (1979), xylazine is not effective in swine.

Toxicity trials in cattle have shown that the median lethal dose of xylazine in adult cattle is three times the highest recommended dose of 0.3 mg/kg. According to Hopkins (1972), this is six times the dose rate indicated for the majority of clinical cases.

IM xylazine (0.08, 0.1, or 0.2 mg/kg) induces a dose-dependent inhibition of reticulorumen contractions in cattle (Ruckebusch and Toutain 1984). Its action is antagonized or quickly reversed by either the IV (0.2 mg/kg) or SC (0.5 mg/kg) administration of tolazoline. Interestingly, omasal activity is increased by xylazine in sheep (Brikas et al. 1986).

Apparently, the effect of xylazine on the body temperature of cattle is variable and may depend on the size of the dose administered. In one study, after IM xylazine (0.4 mg/kg) administration, the body temperature, pulse rate, and respiratory rate exhibited a decrease lasting for almost 24 hours (Dockal et al. 1975). In another study, the body temperature of cattle reached a peak increase (1.9° C) 4–5 hours after IM injection of 0.2 mg/kg xylazine (Young 1979). It remained elevated after 12 hours and did not return to preinjection values until 18 hours after injection (Fig. 14.10).

The type of sedation produced by xylazine in cattle closely resembles that produced by chloral hydrate (Clarke and Hall 1969). Moreover, analgesia is not present except in deeply sedated animals; supplementation with a general or local anesthetic is necessary to prevent movement in response to nociceptive stimuli. More information is needed to establish the efficacy and safety of xylazine in cattle.

Metabolism and Elimination. After IM administration, absorption of xylazine is rapid, with a half-life of 2.8–5.4 minutes (Garcia-Villar et al. 1981). However, it is incompletely absorbed since its bioavailability ranges from 52 to 90% in the dog, 17–73% in sheep, and 40–48% in the horse. Distribution is rapid, with a half-life between 1.2 and 6 minutes. The apparent volume of distribution for xylazine is 1.9–2.7 L/kg in the dog, horse, sheep, and cow (Garcia-Villar et al. 1981).

The half-life of elimination after IV administration of a single dose of xylazine is 49.5 minutes in the horse, 36.5 minutes in cattle, 23 minutes in sheep, and 30 minutes in the dog. Plasma kinetics in cattle are difficult to relate to some of the sustained clinical effects of the drug. The short half-life of xylazine in cattle (36.5 minutes) contrasts with the duration of polyuria (5 hours), hyperthermia (18 hours), hypothermia (24 hours), prostration after a high dose (36 hours), and/or appearance of diarrhea (about 12–24 hours) after injection. Similar to the nonsteroidal anti-inflammatory agents, the plasma half-life or elimination half-life of xylazine cannot be related to these bizarre biochemical and physiologic effects.

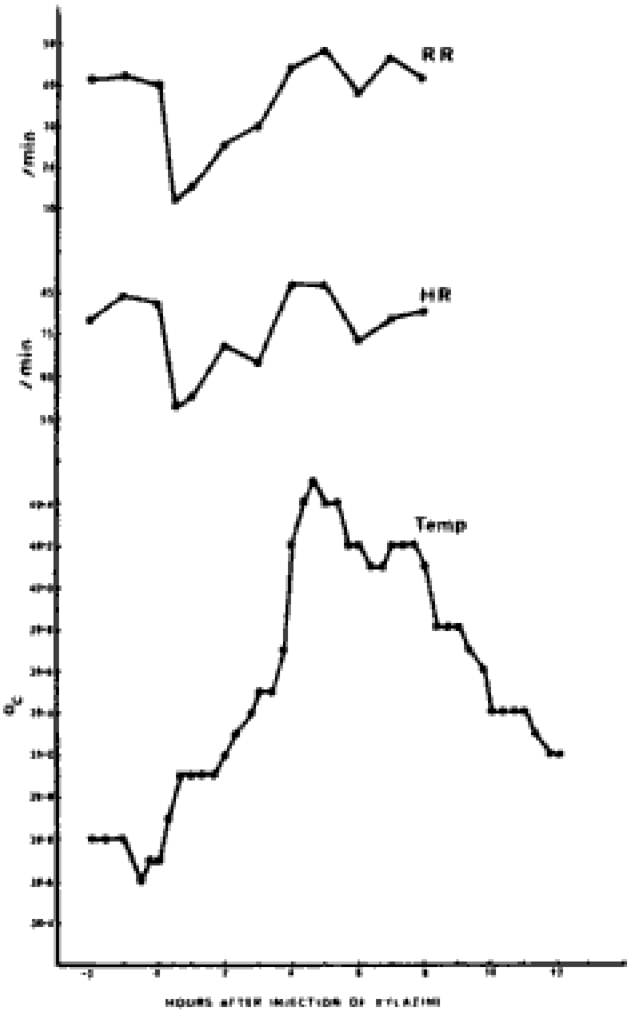

FIG. 14.10.—Effect of IM injection of 0.2 mg/kg xylazine on body temperature, heart rate, and respiratory rate (Young 1979).

In rats, only 8% of the intact, or unchanged, drug appears in urine, whereas in cattle less than 1% unchanged xylazine is eliminated 2 hours after administration (Duhm et al. 1969; Garcia-Villar et al. 1981). Xylazine undergoes rapid metabolism, yielding about 20 metabolites in rats. Peak excretion of metabolites occurs between 2 and 4 hours after administration of xylazine in cattle; this suggests that the drug is extensively metabolized. A metabolite that must form rapidly in cattle is 1,amino-2-6-dimethybenzene (ADB), which appears in urine within 4 hours after an IM dose (therapeutic level) is administered (Pütter and Sagner 1973). ADB probably forms from oxidative or hydrolytic breakdown of the thiazine ring.

PRECAUTIONS AND CONTRAINDICATIONS. Xylazine must not be used in food-producing animals or exist as a drug residue in products (meat, milk, eggs) intended for human consumption. Since xylazine appears to sensitize the heart to epinephrine, administration of epinephrine is contraindicated.

Use of xylazine should be carefully considered when the following complications or conditions exist: (1) cardiac aberrations (xylazine induces arrhythmias and is also a direct depressant of the myocardium), (2) arterial hypotension and/or shock (further enhanced by the hypotensive action as well as reduced cardiac output effect of xylazine), (3) renal impairment (excreted via the kidney), (4) hepatic impairment (apparently the primary degradation of xylazine is dependent upon a functional liver), and (5) epilepsy (may possibly precipitate seizures in susceptible animals).

Animals should be handled carefully after xylazine is administered. A false sense of security may result in injury to personnel because animals can respond by kicking or reacting in other defensive ways. Intra-arterial injection of xylazine should be avoided. See Chap. 12 for discussion of problems associated with intra-arterial injection of anesthetic or tranquilizer agents.

Xylazine must be used cautiously in conjunction with neuroleptics or tranquilizers. Additive depressant effects occur from use of xylazine and barbiturates; use of barbiturates to induce anesthesia must be at a reduced dosage level, and barbiturates must be administered slowly when injected by the IV route. Use of xylazine in combination with ketamine must be carefully considered in animals with cardiopulmonary complications; see discussion in this chapter and Chap. 12.

Sudden death occurred in a nervous Arab stallion suffering from mild colic following IV administration of 1 mg/kg xylazine (Fuentes 1978). Instead of sedation, CNS excitation and convulsions developed (these symptoms are similar to those seen after an intra-arterial injection of xylazine). This was followed by collapse and death about 2 minutes after injection. The action of xylazine during stress and/or release of epinephrine in the horse apparently has not been studied. The effects or interaction of xylazine and epinephrine release in the equine species remain to be determined. A question has arisen about the possibility of epinephrine reversal or hypotension following xylazine. Conversely, xylazine has a hypotensive effect of longer duration than the initial pressor effect in the horse. Hypotensive action of the drug may be responsible for enhancement of the shocklike effect of colic. A cautious approach should be taken whenever xylazine is used in treatment of colic.

Toxicosis in a 6-year-old, 400 kg Standardbred gelding developed after IV injection of xylazine (200 mg) and reserpine (12.5 mg) (Lloyd et al. 1985). A number of side effects, including sporadic episodes of colic, occurred. It is obvious that an undesirable interaction between xylazine and reserpine occurs. This combination of drugs is contraindicated.

Ventricular fibrillation has been reported in one horse after receiving 0.5 mg/kg xylazine intravenously (Steffey et al. 1985). Although the incidence of this happening is considered to be rare, caution needs to be taken in administration of xylazine to animals with cardiac complications.

TABLE 14.1—Xylazine doses

Species	Intravenous	Intramuscular
	(mg/kg)	*(mg/kg)*
Horse	0.5–1.1	1–2
Cattle*	0.03–0.1	0.1–0.2
Sheep*	0.05–0.1	0.1–0.3
Goat*	0.01–0.5	0.05–0.5
Pig	. . .	2–3
Dog	0.5–1	1–2
Cat	0.5–1	1–2
Birds	. . .	5–10

*Lower dose should be used if sedation without recumbency is desired (Knight 1980).

In the dog, two precautions in the use of xylazine need to be emphasized. First, bradycardia, heart block, and severe arterial hypotension can occur; second, bloat (apparently from aerophagia) sometimes develops. Breeds such as the Basset Hound, Great Dane, and Irish Setter appear susceptible to bloat and may require emergency treatment several hours after administration of xylazine. For radiographic restraint, xylazine should be avoided as a sedative because gaseous distention of the stomach will occur; this makes radiographic interpretation more difficult (Folkers 1980).

Debilitated animals with depressed respiration, cardiac disease, renal and liver impairment, shock, or any other stress conditions should be carefully monitored whenever xylazine is administered. The drug is contraindicated in animals within the last month of pregnancy, since it precipitates an early parturition or abortion (Jones 1972). Xylazine should not be administered to dehydrated cattle or those with urinary obstruction (Brown 1986).

DOSAGE. Doses of xylazine recommended in domestic animals are summarized in Table 14.1.

EPIDURAL ADMINISTRATION. In ponies, xylazine has been found to produce more profound and longer-lasting epidural analgesia than lidocaine (Fikes et al. 1988). Xylazine-induced analgesia is not accompanied by the same motor blockade as with local anesthetics (LeBlanc et al. 1988), but xylazine has a significant local anesthetic effect (Aziz and Martin 1978). This effect cannot be blocked by an α_2-adrenergic antagonist, suggesting a membrane-stabilizing effect of locally applied xylazine (O'Regan 1989). In horses, duration of analgesia has been significantly lengthened by coadministration of xylazine and lidocaine (Grubb et al. 1992).

In cattle, the cardiopulmonary depressant effects of epidural xylazine, but not the sedation or regional analgesia, were antagonized with tolazoline, an α_2 antagonist (Skarda et al. 1990). Similar results have been reported in conscious sheep in which dose-dependent regional analgesia of the forelimbs was produced by intrathecally administered xylazine and abolished by intrathecal idazoxan, an α_2 antagonist (Waterman et al. 1988). This would suggest that at least part of the analgesic effect of xylazine is produced through activation of spinal cord α_2 adrenoceptors. This mechanism of analgesia is also supported by prolongation of epidural opioid analgesia with coadministration of other α_2 agonists, such as medetomidine (Branson et al. 1993).

CLINICAL USE

DOGS AND CATS. A commercial preparation containing 20 mg/mL xylazine is available for IV (1.1 mg/kg), IM, or SC (2.2 mg/kg) administration in the dog and cat. In dogs weighing over 22 kg, an IM dose of 1.1 mg/kg is usually recommended for sedation and analgesia. The analgesic effect produced is pronounced over head, neck, and body but is minimal in extremities. With IV barbiturates and inhalant anesthetics, smooth, rapid induction of anesthesia is achieved along with uneventful recovery. The amount of IV barbiturate needed to induce anesthesia is decreased by about one-half or more in the dog and cat. Inhalant anesthetics are also reduced but administered to effect.

Onset of action after IM or SC injection is within 10–15 minutes, and after IV administration it occurs within 3–5 minutes in dogs and cats (Newkirk and Miles 1974). A sedative or sleeplike effect occurs and appears to be dose dependent; this effect usually lasts 1–2 hours. The analgesic effect lasts only 15–30 minutes. Complete recovery from xylazine varies with the dose administered. Recovery is usually complete within 2–4 hours in the dog and cat.

For restraint of the dog in cystometry, an SC dose of xylazine (2.2 mg/kg) is the only drug that has proved adequate without interfering with the micturition reflex (Oliver and Young 1973). Xylazine significantly decreases (26–71%) the amount of pentobarbital required to induce general anesthesia in the dog (Lacuata and Subang 1973). Depth of analgesia produced by xylazine alone is insufficient to permit endotracheal intubation before administration of an inhalant anesthetic; after administration of xylazine, the inhalant anesthetic can be delivered easily with a face mask and then can be followed by intubation (Moye et al. 1973).

IV xylazine (1 mg/kg) and IV ketamine (10 mg/kg) administered 5 minutes afterward is a common combination used in the dog for general anesthesia (Haskins et al. 1986a).

Emesis occurs in the majority of cats 3–5 minutes following administration of xylazine (Moye et al. 1973). An IM dose of 1 mg/kg is considered an optimum level for inducement of emesis in the cat; however, analgesic effects are not observed at this dosage (Amend and Klavano 1973).

In the dog, emesis may also occur following xylazine administered in large doses. The emetic effect is clinically beneficial in emptying the stomach; this prevents the likelihood of vomitus being aspirated into the trachea prior to and during surgery. Xylazine can be used to perform cesarean section under local anesthesia without a depressant effect developing in puppies (Yates 1973). Ketamine hydrochloride has also been used in combination with xylazine for cesarean section and other procedures in the dog (see Chap. 12). Deaths have occurred in two German Shepherds within 24 hours following use of xylazine and ketamine (Kirkpatrick 1978). Both animals were ambulatory and were sent home; they were resting comfortably in the evening only to be found dead by morning. Until more information is available on the safety and efficacy of xylazine-ketamine, caution is suggested in use of these agents (see Chap. 12).

Xylazine premedication is recommended to eliminate muscular hypertonic effects in cats during ketamine anesthesia (Amend et al. 1972; Amend 1973). A combination in which IM xylazine (0.55–1.1 mg/kg) is given as a preanesthetic, followed 20 minutes later with an IM injection of ketamine (15–22 mg/kg), provides analgesia and relaxation in an average of 30 minutes. Xylazine renders the cat relatively insensitive to the pain often associated with injection of ketamine. Ketamine anesthesia in cats is significantly increased by xylazine (Waterman 1983). Additionally, it prolongs the plasma half-life of ketamine (almost doubled, to 69 minutes) and significantly delays formation of the primary metabolite of ketamine.

Also, xylazine (2.2 mg/kg) and ketamine (11 mg/kg) administered intramuscularly are used in cats for surgical procedures requiring general anesthesia of less than 1 hour (Faulk 1978). Since emesis usually follows xylazine injection in most cats within 4–8 minutes or less, ketamine is injected about 10 minutes following injection of xylazine. See Chap. 12 for other information on use of ketamine in combination with xylazine in cats.

HORSES. A commercial preparation containing 100 mg/mL xylazine is available for IV (1.1 mg/kg) or IM (2.2 mg/kg) use in the horse. Xylazine must not be used in horses or other animals intended for human food.

In the horse, doses of about 2 mg/kg xylazine have been given by IM injection 15–20 minutes prior to thiopental sodium or methohexital sodium anesthesia (Clarke and Hall 1969). Two to 3 mg/kg are reported to produce rapid, deep sedation lasting about 30 minutes, followed by rapid recovery. Other clinical reports in the horse pertaining to duration of effect are essentially in agreement with the observations of Clarke and Hall. After an IV injection of xylazine (1.1 mg/kg), onset of effect is noted in 1–1.5 minutes after injection; in 3 minutes the head droops; in 6–6.5 minutes the drug exerts its maximum effect and will continue 10–15 minutes (McCashin and Gabel 1971).

According to McCashin and Gabel (1971), xylazine is more dependable and has resulted in a higher percentage of quieter recoveries from surgical anesthesia in the horse than when promazine hydrochloride or acepromazine maleate is used for preanesthetic medication. They concluded that the most satisfactory dose of xylazine is 1.1 mg/kg intravenously or 2.2 mg/kg intramuscularly. However, weak or debilitated animals should be given a lower dose, particularly if the drug is administered intravenously. Considerably higher doses of xylazine than those recommended rarely produce recumbency in the horse; however, animals may become incoordinated so that it is difficult to work on them (McCashin and Gabel 1971).

Within a very short time after IV injection in the horse, the head characteristically drops or droops. The only disadvantage to this effect is the difficulty in examination of the mouth or passage of the endoscope (McCashin and Gabel 1971). Assisting personnel can hold up the head so that examination of the mouth can be conducted. Hypostatic congestion of nasal mucosa sometimes occurs in the head-down position. Muscle tone of the animal is decreased after administration of xylazine; difficulty in walking occurs soon after the drug is administered intravenously. In colts and geldings, prolapse of the penis sometimes occurs but paraphimosis does not; the effect upon the retractor muscle of the penis is less than that seen with promazine (McCashin and Gabel 1971).

Xylazine administered intravenously (1.1 mg/kg) or intramuscularly (2.2 mg/kg) prior to induction of anesthesia either with thiamylal or with thiamylal and halothane is a satisfactory preanesthetic agent in the horse; less respiratory depression and greater cardiovascular stability follow use of xylazine than with IV administration of 0.66 mg/kg acepromazine (Kerr et al. 1972a). Of the drugs evaluated in the horse, xylazine in the presence of epinephrine release is less likely to produce tachycardia than acepromazine (Aitken and Sanford 1972). For other information on the use of thiamylal with xylazine, see the 7th edition of this text.

For preanesthetic purposes in the horse, IV xylazine is administered at a dose of 0.55–1.1 mg/kg (Short 1974). In addition, atropine (0.045 mg/kg) is administered subcutaneously or intramuscularly.

Hoffman (1974) found the sedative and analgesic effects to be good to excellent in 88 and 81% of the horses respectively following IV administration of xylazine; the optimal dose is 1.1 mg/kg. The quantity of general anesthetic needed is the same as when promazine is used as a preanesthetic medication. Although recovery is rapid and smooth after general anesthesia of short duration, it is too rapid and often violent when anesthesia is prolonged for 45 minutes or more (Hoffman 1974).

Klein and Baetjer (1974) as well as Klavano (1975) have found that combined use of xylazine and morphine provides satisfactory sedation and analgesia in the standing horse. Xylazine (1.2 mg/kg) is administered intravenously; this is followed 5–10 minutes later with IV injection of morphine (0.75 mg/kg). These drugs are useful for suturing wounds and external surgical procedures. Aspiration or injection is possible into the joint of a horse that would otherwise not tolerate such a procedure. As effects of xylazine disappear, animals may become excitable and restless. IV administration of levallorphan tartrate (0.022 mg/kg) is recommended to relieve or prevent excitable effects of morphine (Klavano 1975). For preanesthethic purposes, xylazine (0.22 mg/kg) and morphine (0.12–0.6 mg/kg) have been used intravenously.

Xylazine (1.1 mg/kg) is administered intravenously about 4 minutes prior to IV ketamine (1.65 mg/kg for ponies and 2.2 mg/kg for horses). This combination provides satisfactory induction of anesthesia for tracheal intubation (Ellis et al. 1977).

Xylazine (1.1 mg/kg) given intravenously, followed in 2–3 minutes by IV ketamine (1.65–2.2 mg/kg) provides 12–15 minutes of surgical anesthesia in the horse (Heath 1977). An IV dose of 1.65 mg/kg ketamine results in about 10–12 minutes of recumbency, while 2.2 mg/kg intravenously provides 15 minutes and occasionally up to 20–25 minutes. Xylazine (2.2 mg/kg) is used intramuscularly 20 minutes prior to IV administration of guaifenesin (55 mg/kg) in 5% dextrose. Immediately after induction of anesthesia with guaifenesin, IV ketamine (1.7 mg/kg) is administered (Muir et al. 1978). Anesthesia can be maintained with inhalant anesthetics such as halothane or enflurane.

Xylazine has also been used in combination with ketamine and diazepam for short-term anesthesia in horses. Dosages of these drugs are covered in Chap. 12 under clinical uses of ketamine in horses. Since there is increased risk of using a combination of xylazine and ketamine in animals afflicted with cardiopulmonary complications, caution is advised whenever this combination of drugs is administered.

Xylazine (1.1 mg/kg) has been used prior to induction of thiopental (4.4 mg/kg) anesthesia in the horse (Butera et al. 1980). It is given intravenously 2.5 minutes before IV thiopental (10%). Within 1–2 minutes the horse quietly becomes recumbent. Approximately 15–20 minutes of effective analgesia appears to be provided by this combination of drugs. Minor surgical procedures such as castrations, suturing lacerations, and removal of cutaneous tumors can be carried out following administration of xylazine and thiopental. If necessary, inhalant anesthetics can be administered to maintain surgical anesthesia.

Xylazine (0.055 mg/kg) given intravenously is recommended for dental examination of the horse (Scoggins 1979). Doses in excess of this result in oversedation and cause an undesirable dropping of the head.

Xylazine also has been used successfully in supportive therapy for controlling seizures following *Clostridium tetani* infections in horses (Beroza 1980). A number of analgesics have been compared for their efficacy in an experimental colic model. Lowe (1982) has found that xylazine is the best analgesic agent for prompt effect in alleviating the pain of colic. Since xylazine has an arterial hypotensive component that possibly could enhance the shocklike effect of severe colic, a cautious approach is advised whenever it is used for this treatment.

CATTLE. Xylazine is not approved by the FDA for use in cattle and has been the subject of several malpractice suits in the USA (Ames 1979). It would be easy to overdose cattle, since they require only one-tenth the dose of xylazine on a body weight basis as horses, dogs, and cats.

Rickard et al. (1974) administered xylazine (0.22 mg/kg) and atropine (0.044 mg/kg) intramuscularly in bulls of mixed breeding; the ages of the animals were 15–24 months and body weights were 500–600 kg. Ten to 15 minutes after administration of xylazine, the animals became recumbent in the sternal position. They were then placed in lateral recumbency and restrained with a halter and leg ropes in preparation for electroejaculation and semen collection. In a fourth series of semen collections, xylazine in a dose of 0.22 mg/kg was observed to be less effective. Inasmuch as the animals attempted to stand during the electrostimulation, an additional 20–40 mg of the drug were administered to maintain restraint. With semen collection extending through a 3-week period that required repeated administration of xylazine, this additional dosage could possibly indicate that induction of microsomal enzyme activity had occurred. If so, a more rapid degradation and metabolism of the drug would result. Also, the decreased response could be due to xylazine or agonist-induced decreases in α_2-adrenergic cell receptors. A decrease in the cell receptor number is referred to as "down-regulation" by molecular pharmacologists.

An IM dose of xylazine (0.09–0.35 mg/kg) produces light to deep sedation in cattle (Hopkins 1972). Intravenously, xylazine (0.05–0.1 mg/kg) produces basal narcosis in cattle for 1–2 hours (Clarke and Hal 1969). Sedation and slight muscle relaxation with the animal in the standing position were reported following an IM dose of 0.05 mg/kg (Jones 1972). Xylazine (0.1 mg/kg) at increased IM dosages produces good sedation, marked muscle relaxation, and some analgesia; this dosage ordinarily allows the animal to remain in the standing position but may result in recumbency. At still higher IM doses of xylazine (0.2 mg/kg), deep sedation and a useful level of analgesia are induced, with the animal usually lying down. Following administration of this dose, the first effects are noted within 5 minutes and the maximum effect is induced 10 minutes later (Jones 1972).

Xylazine induces a marked degree of salivation in ruminants. Preanesthetic medication with atropine partially reduces this problem and is recommended when large doses of xylazine are used (Knight 1980).

Ruminal atony, bloating, and regurgitation with aspiration pneumonia may occur in cattle following use of xylazine. Cattle should be monitored for about 2 hours after xylazine administration for signs of bloat (Brown 1986). It is advisable to fast cattle for 24 hours before injection of xylazine to lessen the risk of regurgitation. Loose feces and liquid hemorrhagic diarrhea, including recumbency for about 1 hour, have occurred in large bulls following a sedative dose of xylazine (Knight 1980). Diarrhea may appear about 12–24 hours after injection. It is of a transitory type in most cases and believed to be due to ruminal and intestinal stasis during sedation. Also, xylazine induces a marked polyuria in many animals.

In lactating cows, IM doses (0.2 or 0.4 mg/kg) of xylazine do not result in detectable concentrations in milk at 5 and 21 hours after injection; cows ostensibly do not excrete xylazine in milk (Pütter and Sagner 1973). However, lactating animals must not receive xylazine, according to the FDA, when milk is sold for human consumption.

In the calf, use of xylazine-ketamine results in an undesirable and potentially dangerous reduction in P_aO_2. It is recommended that supplemental oxygen be given to calves receiving xylazine-ketamine anesthesia (Ring and Muir 1982).

SWINE. A xylazine-ketamine combination has been used in the pig (see Chap. 12). More data are needed in this species to determine the safety and efficacy of this combination of drugs.

GOATS. Xylazine (0.1 mg/kg) administered intravenously provides deep sedation in goats that lasts 30–35 minutes. It has been used in combination with ketamine for induction of anesthesia (see Chap. 12).

LABORATORY ANIMALS. A combination of xylazine and ketamine has been used in rats and rabbits to induce short-term anesthesia (see Chap. 12).

In the mouse, a combination of 1 mL xylazine (100 mg/mL) and 1 mL ketamine (100 mg/mL) is added to 4.6 mL sterile water (Mulder and Mulder 1979). The total volume of the mixture is 6.6 mL. An adult mouse averages about 30 g. For each 30 g of body weight, 0.1 mL (1.5 mg each of xylazine and ketamine) of the combination is used to provide 50 mg/kg of each drug. At this dosage, adequate anesthesia is maintained for 60–100 minutes after a single IM injection in C57BL and DBA mice. This length of anesthesia provides sufficient time to complete most surgical procedures.

FISH. Although xylazine is effective as an anesthetic in fish, it cannot be recommended because of its convulsant activity during induction and recovery (Ostwald 1978).

AVIAN AND EXOTIC SPECIES. Xylazine has been used in nine avian species (Levinger et al. 1973). Following IM injection, xylazine produces a marked sedative effect in birds. IM doses of 1–2 mg/kg xylazine produce no change in behavior. At doses above 5 mg/kg, signs of CNS depression occur. Light sedation is induced with xylazine in the chicken and turkey at 10 mg/kg administered intramuscularly (Levinger et al. 1973). Xylazine has been used in combination with ketamine and althesin to induce anesthesia in ostriches (see Chap. 12).

Xylazine has been used in a large number of exotic species (Bauditz 1972); however, in the past lack of a suitable antidote has been a serious shortcoming in reversal of its action. Recovery of immobilized animals requires 2–3 hours before ambulation is attained (Young and Whyte 1973). Experimental studies completed in dogs (Hatch et al. 1982) and cattle (Kitzman et al. 1982) have shown that xylazine can be antagonized by IV administration of 4-aminopyridine and yohimbine hydrochloride. It is possible that these antagonists will serve importantly in reversal of the immobilizing effects of xylazine in exotic species. For additional information on antagonists that reverse the action of xylazine, see Chap. 16.

The most important value of xylazine pertains to its excellent synergistic properties when used in combination with potent analgesics such as etorphine hydrochloride or fentanyl citrate. Moreover, it markedly potentiates the immobilizing action of ketamine.

Sedation and immobilization doses of xylazine administered by projectile syringe or intramuscularly are listed for some of the exotic species (Table 14.2). The drug has also been used in combination with ketamine for induction of anesthesia (see Chap. 12). Also refer to the precautions discussed for use of the combination of xylazine and ketamine.

Giraffes are extremely sensitive to xylazine, and its sole use does not permit safe manipulative procedures in this species (Bush et al. 1976). However, its use in conjunction with etorphine produces desirable restraint or immobilization.

In fallow deer, a fatal hyperthermia greater than 44° C occurred following use of xylazine and etorphine (Pertz and Sundberg 1978). It is not known whether other exotic species may be similarly affected by this combination. Hyperthermia in exotic animals has been seen chiefly following use of promazine tranquilizers alone and in combination with morphomimetic agents.

For restraint of Bactrian camels, IM xylazine (0.27–0.51 mg/kg) provides adequate sedation for tuberculin testing and other procedures (Custer et al. 1977). In an elephant weighing about 3500 kg, IM xylazine (400 mg) given into the triceps muscle induced immobilization (Robinson and Meier 1977).

Baby African elephants have been successfully sedated and immobilized by xylazine (Trembath 1984); IM doses are as follows:

Weight (kg)	*Light sedation (mg)*	*Immobilization (mg)*
180	20	40
300	80	120
450	120	160

Xylazine has been used in combination with etorphine for immobilization of polar and brown bears. For the dosages used, see Chap. 13.

Use of xylazine for immobilization of Reeves' muntjac (*Muntiacus reevesi*) is unpredictable in its effect (Cooper et al. 1986). Prolonged recovery of the animals limits its value for use under field conditions.

Detomidine Hydrochloride. *Detomidine hydrochloride* ([4-(5)-(2,3-dimethylbenzyl) imidazole hydrochloride]; Dormosedan) (Fig. 14.11) is a

TABLE 14.2—Sedative and immobilizing doses of xylazine for exotic species

Species	Dose Sedation	 Immobilization
	(mg/kg)	
Fallow deer (*Dama dama*)	1–2	5–8
Red deer (*Cervus nippon*)	2	3–4*
Roe deer (*Capreolus capreolus*)	0.5–1	1.5–3
White-tailed deer (*Odocoileus virginianus*)	0.5–1	3–4
Elk (*Alces alces*)	0.5	1.5
Reindeer (*Rangifer tarandus*)	0.5	2
Greater kudu (*Tragelaphus strepsiceros*)	1	3
Bushbuck (*Tr. spekei*)	1.5	3
Eland (*Taurotragus oryx*)	1	3
Sable antelope (*Hippotragus niger*)	1.5	3
Gazelle (*Gazella* sp.)	1	2–4
Water buffalo (*Bubalis arnee*)	0.5–1	1–2(?)
Yak (*Bos mutus*)	0.3	0.6–1
American bison (*Bison bison*)	0.1–0.3	0.6–1
Musk ox (*Ovibos moschatus*)	<0.5	0.5–1.5
Dromedary (*Camelus dromedarius*)	0.1	0.5
Llama (*Lama guanicoe glama*)	0.2–0.5	1–2
Bear (most species)	2–6	8–10
Striped hyena (*Hyaena striata*)	3–5	7–8
Wolf (*Canis lupus*)	3–5	7–8†

Leopard, spotted (*P. pardus*)	. . .	8–10
Cheetah (*Acinonyx jubatus*)	. . .	2(?)
Zebra (*Equus quagga*)	3–5	. . .
Subhuman primates (many species)	0.5–1	2–5

*If 3–4 mg/kg as recommended by the manufacturer is used in Isle of Rhum red deer off the west coast of Scotland, a coma lasting 6–9 hours occurs (Fletcher 1974). The correct dose for Rhum red deer is 0.1–0.2 mg/kg. The marked hypersensitivity of the animals to xylazine compared to mainland red deer may possibly be due to a high degree of inbreeding.

†The effective dose range for captive Arctic wolves is 3–6.8 mg/kg (Philo 1978).

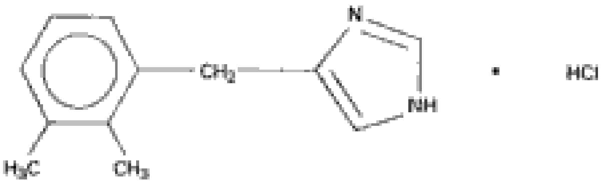

FIG. 14.11.—Detomidine Hydrochloride

sedative-analgesic that was originally developed for use in horses and cattle (Virtanen et al. 1985). Detomidine is more potent than xylazine, with greater specificity at central α_2 adrenoceptors (Virtanen and MacDonald 1985), although very high concentrations will activate α_1 adrenoceptors (Virtanen and Nyman 1985).

Detomidine induces cardiovascular effects similar to xylazine. Decreased myocardial contractility, bradycardia, and a biphasic blood pressure response may occur after IV injection (Wagner et al. 1991). The bradycardia is commonly accompanied by first- or second-degree AV block. These effects may be alleviated by anticholinergic administration (Short et al. 1986).

Detomidine (10–60 µg/kg IV) produces cardiovascular changes in horses that are nearly identical to those produced by xylazine (1.1 mg/kg IV) (Sarazan et al. 1989). Sedation and analgesia produced by detomidine are of longer duration than those produced by xylazine in equivalent doses (Jochle and Hamm 1986; Clarke and Taylor 1986). Detomidine (20 µg/kg IV) induced 45 minutes of analgesia and sedation in a cecal balloon colic model, whereas the equianalgesic dose of xylazine (1.1 mg/kg IV) was effective for only 20 minutes (Lowe and Hifiger 1986). It is not uncommon to observe good sedation for 90–120 minutes and analgesia for 75–80 minutes after a 40 µg/kg IV dose of detomidine. For this reason, it has been suggested that detomidine is the analgesic of choice for relieving equine colic pain (Tranquilli and Maze 1993).

Detomidine is an effective preanesthetic for horses and cattle and can be used in combination with ketamine to induce short periods of anesthesia (Clarke and Taylor 1986; Clarke et al. 1986a). The combination of detomidine with Telazol (tiletamine and zolazepam, see Chap. 12) has proven to be an effective combination in horses and ponies (Wan et al. 1992; Lin et al. 1992). Recovery from inhalation anesthesia is usually uneventful in horses premedicated with detomidine. As with xylazine, hyperglycemia and increased urine output may occur after detomidine administration (Tranquilli and Maze 1993).

Concurrent administration of an α_2-adrenergic agonist may diminish or eliminate the excitation that occurs with opioid use in horses. Opioid stimulation was not observed when detomidine was combined with methadone, morphine, meperidine, or butorphanol (Clarke and Paton 1988). The combination of detomidine and butorphanol may provide the most effective sedation and analgesia while minimizing cardiopulmonary depression (Clarke and Paton 1988; LeBlanc 1991). Detomidine (10–15 μg/kg IV) injection precedes butorphanol (20–30 μg/kg IV) injection. The full effect should be allowed to develop prior to start of the procedure. Sedation is accompanied by ataxia, slight tremor of the face and lips, and a tendency to lean forward and head press (Tranquilli and Maze 1993). Detomidine is approved for use in horses in the USA.

Medetomidine Hydrochloride. Chemically, *Medetomidine hydrochloride* is (±)-4-[1-(2,3-dimethylphenyl)-ethyl]-1*H*-imidazole monohydro-chloride (Domitor) (Fig. 14.12). Medetomidine is the most potent α_2-adrenoceptor-selective agonist available for use in veterinary medicine. The α_2/α_1 receptor selectivity binding ratio for medetomidine is 1620, compared to 260 and 160 for detomidine and xylazine, respectively (Virtanen 1989). It produces sedation, muscle relaxation, and analgesia in a variety of domesticated species. Variability in effects among species seems to be less for medetomidine than for xylazine, a less-specific α_2 agonist.

Medetomidine induces dose-dependent sedation and analgesia in dogs and cats (Vainio 1989). As with xylazine and detomidine, administration of additional drug increases the duration of effect but does not result in more sedation.

Profound sedation and bradycardia consistently occur in dogs administered 40 μg/kg of medetomidine intramuscularly (Raiha, M. P., et al. 1989; Vainio and Palmu 1989). In dogs not premedicated with atropine, blood pressure decreases in a dose-dependent manner after administration of 10–60 μg/kg of medetomidine (Bergstrom 1988).

Prior administration of an anticholinergic may be more effective at preventing the bradycardia than reversing the bradycardia after it has occurred (Short 1991), but it may increase the initial hypertensive effect that occurs during onset of sedation (Vainio 1989; Bergstrom 1988). Duration of sedation in cats is dose dependent, although bradycardia is not (Stenberg 1989). When combined with ketamine, the bradycardic effect of medetomidine may be offset by the sympathomimetic properties of the dissociative (Verstegen et al. 1991).

Respiration rate decreases in a dose-dependent manner after administration of 10–60 μg/kg of medetomidine in dogs (Bergstrom 1988). A 20 μg/kg IV infusion of medetomidine results in less depression of the hypercapnic response curve in dogs than 1 minimum alveolar concentration (MAC) isoflurane (1.38%) anesthesia (Bloor et al. 1989)). End-tidal CO_2 and P_aCO_2 values were decreased significantly in dogs administered medetomidine versus those administered isoflurane anesthesia.

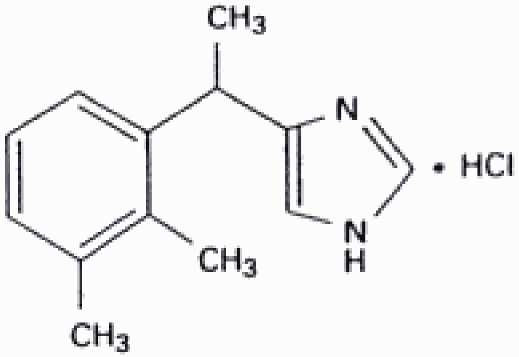

FIG. 14.12.—Medetomidine Hydrochloride

IM or SC administration of medetomidine may result in vomiting in dogs and cats (Virtanen 1989). Diuresis occurs even with low doses (10 μg/kg), producing large amounts of dilute urine (Crighton 1990).

IM medetomidine at a dose of 30 μg/kg provides sedation and analgesia in dogs equivalent to a 2.2 mg/kg dose of xylazine. Combinations of medetomidine and ketamine have provided short periods of anesthesia and immobilization in dogs, cats, and many laboratory and exotic animal species (Vähä-Vahe 1989; Jalanka 1989, 1990; Nevalainen et al. 1989; Arnemo and Soli 1992; Van Heerden and Keffen 1991). Medetomidine (40 μg/kg) combined with 5.0 mg/kg of ketamine produces anesthesia in dogs comparable to that produced with 1 mg/kg xylazine and 15 mg/kg ketamine (Moens and Fargetton 1990). Dogs premedicated with medetomidine (20–40 μg/kg) have been administered propofol (2 mg/kg loading dose; 165 μg/kg/min), etomidate (0.5 mg/kg loading dose; 50 μg/kg/min), or ketamine (4 mg/kg IV) for maintenance of anesthesia (Thurmon et al. 1995; Ko et al. 1994; J. E. Raiha et al. 1989).

Medetomidine produces greater ataxia at equal sedative/analgesic doses in horses than xylazine or detomidine. Consequently, xylazine or detomidine may be the preferred α_2 agonists for use in horses (Kamerling et al. 1991; Bryant et al. 1991).

Medetomidine produces more predictable sedation and analgesia in swine than does xylazine (Sakaguchi et al. 1992). Medetomidine doses of 30–80 μg/kg produce sedation in pigs. As with dogs and cats, higher doses do not produce increased sedation.

Similar to xylazine and detomidine, the administration of medetomidine with an opioid may enhance sedation and analgesia beyond that expected with either drug alone (England and Clarke 1989). Medetomidine is approved for veterinary use in dogs and cats in the USA.

New α_2-Adrenergic Agonists. Romifidine is the newest α_2-adrenergic agonist assessed for sedative and analgesic activity in the horse. Romifidine (80 µg/kg) produces sedation similar to xylazine (1 mg/kg) or detomidine (20 µg/kg). Xylazine and detomidine produce greater ataxia and sedation of shorter duration than romifidine (England et al. 1992).

Dexmedetomidine is a very selective α_2-adrenoceptor agonist whose role as an anesthetic adjunct in veterinary medicine is still being defined.

α_2-Adrenergic Antagonists. The incidence of unfavorable reactions to α_2-adrenoceptor antagonists is rare when they are administered appropriately for reversal of α_2-adrenoceptor agonist-induced CNS depression. Deaths have been reported after rapid IV administration of high doses of tolazoline and yohimbine (Hsu et al. 1987). Acute and delayed death has occurred in llamas administered tolazoline. Profound hypotension and tachycardia may occur after rapid IV injection but may be prevented by slow administration to the desired effect. Anxiety, pacing, and panting in dogs, and hyperexcitement in cats or very young animals, have occurred with administration of yohimbine. Diarrhea and piloerection have occurred in dogs after administration of tolazoline. Other species differences in response to α_2-adrenoceptor antagonists have not yet been established.

YOHIMBINE. *Yohimbine* (17-hydroxyyohimban-16-carboxylic acid methyl ester; Yobine, Antagonil) (Fig. 14.13) is an α_2-adrenoceptor antagonist that is approximately 60 times more selective for the α_2 than the α_1 adrenoceptor (Clarke et al. 1986b). It antagonizes α_2-adrenoceptor-mediated depression and enhances the release of norepinephrine and other excitatory neurotransmitters (Tranquilli and Maze 1993). Yohimbine has been effective in antagonizing α_2-agonist-induced sedation and analgesia in many species (Holmberg and Gershon 1961; Lang and Gershon 1963; Delbarre and Schmitt 1971, 1973).

Yohimbine administered alone has proven effective in reversing the sedative-immobilizing effects of anesthetic combinations incorporating xylazine (Jessup et al. 1985; McGruder and Hsu 1985; Hsu 1985; Hsu et al. 1986; Jacobson et al. 1985; Hsu and Shulaw 1984; Jessup et al. 1983). Yohimbine administered in conjunction with 4-aminopyridine effectively induced anesthetic reversal in many domestic and wild species (Hatch et al. 1982; Kitzman et al. 1984; Wallner et al. 1982; Hatch et al. 1983a; Cronin et al. 1983a; Kitzman et al. 1982; Hatch et al. 1983b; Hatch et al. 1984). Yohimbine is approved for use in dogs (Yobine) and wild, exotic, and ranched deer (Antagonil). Antagonism of the effects of xylazine is also discussed in Chap. 16.

TOLAZOLINE. *Tolazoline* (2-benzyl-2-imidazoline; Priscoline) (Fig. 14.14) has been used in a number of species to reverse xylazine sedation or to partially reverse the depressant effects of xylazine when administered as part of an anesthetic regimen (Hsu et al. 1987; Allen and Oosterhuis 1986; Kreeger et al. 1986a; Kreeger et al. 1986b; Allen 1986; Tranquilli et al. 1984; Thurmon et al. 1989). Tolazoline is the least specific antagonist for α_2 adrenoceptors but may be more effective than yohimbine at antagonizing some of the effects of xylazine. In cats sedated with xylazine, tolazoline induced a calmer recovery (Hartsfield et al. 1986), and it was more efficient in decreasing the time to recovery in calves sedated with xylazine (Thurmon et al. 1989). Tolazoline also induces potent H_2-receptor agonist actions, and chronic use in humans has been associated with GI bleeding and other complications (Silverman et al. 1970). Sudden unexplained death, both acute and delayed, has occurred in llamas administered tolazoline. It has been suggested that the cause is a combination of hypotensive shock and bradycardia. Further investigation is necessary to define the use of tolazoline in llamas. Tolazoline has not been approved for veterinary use.

ATIPAMEZOLE. *Atipamezole hydrochloride* (4-(2-ethyl-2,3-dihydro-1*H*-inden-2-yl)-1*H*-imidazole hydrochloride; Antisedan) (Fig. 14.15) has greater α_2-adrenoceptor specificity and may be more effective in antagonizing the effects of α_2 agonists. It has an α_2/α_1 selectivity ratio that is 200–300 times greater than that of yohimbine and is devoid of activity at other types of receptors (Virtanen et al. 1989). Dosage recommendations for atipamezole vary among species and for various α_2 agonists (Tranquilli and Maze 1993). For example, a xylazine dose of 0.3 mg/kg in calves is reversed

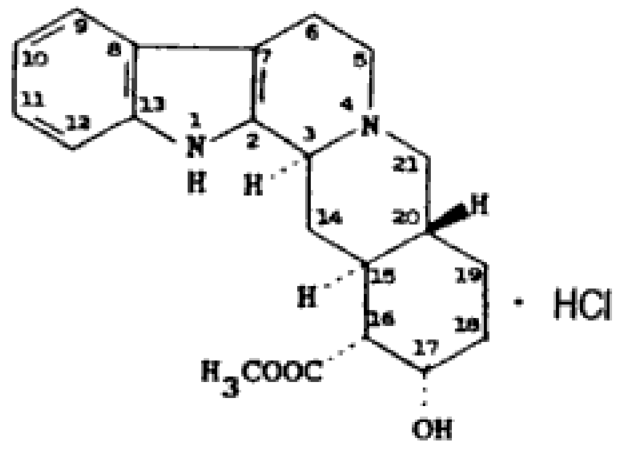

FIG. 14.13.—Yohimbine Hydrochloride

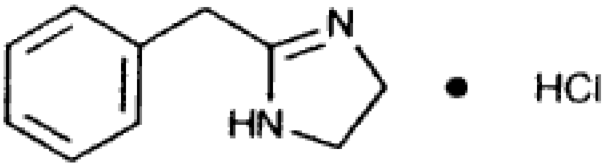

FIG. 14.14.—Tolazoline Hydrochloride

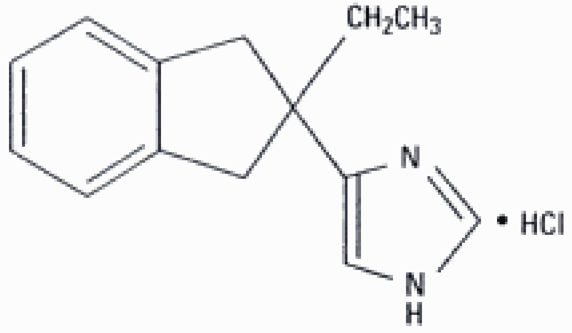

FIG. 14.15.—Atipamezole Hydrochloride

by an atipamezole dose of 30 µg/kg (Thompson et al. 1991, but a medetomidine dose of 40 µg/kg in a dog requires 160–240 µg/kg of atipamezole for reversal (Vähä-Vahe 1990).

In horses administered atipamezole at 10 times the administered dose of detomidine or medetomidine, mydriasis and analgesia were abolished, but bradycardia and sedation were only transiently influenced (Kamerling et al. 1991). The administration of atipamezole alone in horses produces mild sedation and myocardial depression without analgesia, as well as consistent dose-related changes in behavior and autonomic variables. Atipamezole-induced sedation in the dog or cat has not been reported. Atipamezole is approved for IM use in dogs.

BENZODIAZEPINE DERIVATIVES

The Benzodiazepine Receptor. Benzodiazepine derivatives used in veterinary medicine include diazepam, midazolam, zolazepam (in combination with tiletamine as Telazol, see Chap. 12), and chlordiazepoxide.

Based on electrophysiologic investigations, it is believed that benzodiazepines produce hypnotic, sedative, anxiolytic, anticonvulsant, and skeletal muscle–relaxant effects by enhancing the action of the neurotransmitter γ-aminobutyric acid (GABA) on its receptors (Polc 1988). GABA type A, or $GABA_A$, receptors are membrane-associated glycoproteins that exhibit some similarity to nicotinic acetylcholine, glycine, and 5-hydroxytryptamine type 3 receptors (Darlison and Albrecht 1995). The $GABA_A$ receptor comprises five (pentameric) protein subunits, of which several different types have been identified: six α, four β, three γ, one δ, and two ρ subunits (Sieghart 1994).

The benzodiazepine receptor is a modulatory site on the $GABA_A$ receptor that allosterically regulates the postsynaptic chloride channel gating that occurs with the interaction of GABA with $GABA_A$ receptors (Olsen and Tobin 1990; Sieghart 1994). Modulation of $GABA_A$-receptor activity occurs only at submaximal concentrations of GABA. That is, benzodiazepines have no modulating effect at the $GABA_A$ receptors when the GABA concentration reaches saturation level (Haefely 1989). The modulation of $GABA_A$-receptor activity may be either positive or negative (Polc et al. 1982). Positive modulation occurs with the binding of anxiolytic compounds such as benzodiazepine agonists. Negative modulation occurs with the binding of inverse agonists, which are anxiogenic. A third group of high-affinity ligands, the benzodiazepine-receptor antagonists, have only a weak or no intrinsic activity for modulating $GABA_A$ activity but are able to inhibit the effects of both benzodiazepine-receptor agonists and inverse agonists. Partial agonists and partial inverse agonists have also been identified (Haefely et al. 1985).

It has been demonstrated that only the combination of α, β, and γ subtypes results in $GABA_A$ receptors that may be modulated by benzodiazepines (Pritchett et al. 1989). In addition, the benzodiazepine pharmacology of the $GABA_A$ receptors is determined by the α and γ subunits that are present. The presence of the γ_2 subunit yields receptors with high-affinity binding for benzodiazepine agonists, the benzodiazepine antagonist flumazenil, and the inverse agonist DMCM (β-carboline methyl-4-ethyl-6,7-dimethoxy-β-carboline-3-carboxylate). The presence of the α_1 subunit allows binding of certain substances (triazolopyridazine compounds, β carbolines) with higher affinity than receptors possessing either an α_2 or α_3 subunit do (Pritchett et al. 1989).

Both central and peripheral benzodiazepine receptors have been described (Zisterer and Williams 1997). The central type is present exclusively in the CNS and is localized to neurons (Young and Kuhar 1979). At least two central benzodiazepine receptor subtypes have been described: the BZI receptor, located predominantly in the cerebellum; and the BZII receptor, located in the hippocampus and some other brain regions. $GABA_A$ receptors containing an α_1 subunit (together with the β_1 and γ_2 subunits) are associated with the BZI binding sites. Those $GABA_A$ receptors with either the α_2 or the α_3 subunit are associated with the BZII binding sites. The binding of benzodiazepines to the central benzodiazepine receptors is stimulated in the presence of GABA and other $GABA_A$ receptor agonists (Karobath et al. 1981). Reciprocally, the binding of GABA to $GABA_A$ receptors is enhanced by the presence of benzodiazepines (Bristow et al. 1990; Skerritt et al. 1982). The peripheral type benzodiazepine receptors were initially discovered in peripheral tissues (rat kidney, liver, lung) (Braestrup and Squires 1977), but later studies demonstrated their presence in the CNS also (Schoemaker et al. 1981). The peripheral receptors are pharmacologically distinct from and unrelated to the $GABA_A$-receptor-associated benzodiazepine receptors (Zisterer and Williams 1997; Sieghart 1994).

$GABA_A$ receptors are also associated with binding sites for other substances. In addition to benzodiazepine receptor binding sites, there are also binding sites for barbiturates, certain steroids and channel blockers, and the anthelmintic avermectin B1a

(McDonald and Olsen 1994; Sieghart 1992). Both barbiturates and benzodiazepines potentiate the effects of GABA, but the barbiturates prolong the open time of the chloride ion channel, whereas benzodiazepine agonists increase the frequency of channel opening (McDonald and Olsen 1994).

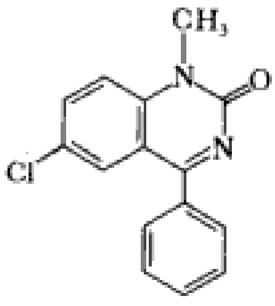
In 1977, Claus Braestrup and Richard Squires discovered that the brain has its own specific receptor for benzodiazepines. Use of radioactively labeled benzodiazepines has demonstrated that there are high-affinity binding sites in the mammalian brain (associated with synaptosomal membranes) that fulfill many of the criteria of pharmacologic receptors for these compounds. Benzodiazepine receptors appear to have widespread distribution in the brain. Interestingly, lack of receptors in white matter is a consistent finding in all species. In addition to the presence of benzodiazepine receptors in the brain, receptors are also present in peripheral tissues, including kidney, liver, heart, and lung (Gee et al. 1984).

Widespread distribution of benzodiazepine receptors in the CNS contrasts with the more discrete localization of other receptors (e.g., opiate receptors). This fits evidence from behavioral and electrophysiologic studies that benzodiazepines interact at many levels of the brain to elicit their effects (Tallman et al. 1980). It has also been suggested that different receptor subtypes mediate the different actions of the benzodiazepines. The anxiolytic, anticonvulsant, and muscle relaxation effects are believed to be mediated at the benzodiazepine $GABA_A$ receptor, whereas the hypnotic effects may be mediated by alterations in a potential-dependent calcium ion flux (Mendelson 1992). The different actions may also be a function of blood levels, with the anxiolytic effect occurring at lower levels, and sedation and unconsciousness occurring with increasing blood levels (Amrein et al. 1988).

Interactions between the benzodiazepine receptor and anions also occur. Chloride, bromide, iodide, nitrite, and thiocyanate (but not fluoride) enhance binding of diazepam. Sedative action of the once used and now obsolete drug sodium bromide may have induced its effect at this level.

Embryologically, the benzodiazepine receptor is present at 14 days of gestation in the rat, and the number of receptor sites increases in parallel with GABA-receptor recognition sites.

The benzodiazepine receptor is associated with the anxiolytic and anticonvulsant actions of benzodiazepines. Two strains of rats, bred for high and low fearfulness, have significantly different densities of brain benzodiazepine receptors. Inasmuch as these two strains differ in their emotionality, differences in receptor number may be physiologically important in regulation of anxiety or apprehension (Robertson et al. 1978). Binding of benzodiazepines is also altered in spontaneous epilepsy in the baboon (Squires et al. 1979), and an increase in the number of benzodiazepine receptors has been reported in rats following experimentally induced seizures (Paul and Skolnick 1978). These alterations in number of receptors are comparable to those seen in other CNS receptors after treatments designed to alter neuronal input (Skolnick et al. 1978). Rapid onset (within minutes) of alterations in benzodiazepine receptors and their return to control levels (within 1 hour) is rather remarkable (Tallman et al. 1980). Such alterations in other central CNS receptors generally occur over a time frame of days.



Diazepam

FIG. 14.16

Diazepam. Chemically, *Diazepam*, USP (Valium), is 7-chloro-1,3-dihydro-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one (Fig. 14.16). A major disadvantage of diazepam is its insolubility in water. Diazepam and other benzodiazepines are classified as Schedule IV agents under the 1970 Controlled Substances Act.

CENTRAL NERVOUS SYSTEM. Benzodiazepines are thought of as "disinhibitors" of suppressed behavior; they induce taming effects in animals. They modify behavior in both humans and animals. In humans, benzodiazepine derivatives (diazepam, chlordiazepoxide, and flurazepam, referred to as Dalmane) are used widely in clinical practice as muscle relaxants, anticonvulsants, anxiolytics, and hypnotics (especially flurazepam sleeping pills). Like most psychotropic agents, benzodiazepines produce undesirable effects (e.g., ataxia) that may or may not be related to their therapeutic effects (Tallman et al. 1980).

Of the benzodiazepine derivatives diazepam is about 20 times more potent than chlordiazepoxide in blocking decerebrate rigidity in animals. The principal site of CNS depression produced by diazepam is the brain stem reticular formation.

In decerebrate cats, polysynaptic reflexes elicited by sciatic nerve stimulation can be depressed to 50% or less by IV administration of diazepam (0.05–0.2 mg/kg), chlordiazepoxide (10–30 mg/kg), and pentobarbital (24 mg/kg); blockade of polysynaptic reflexes by these drugs is immediate and lasts up to 4 hours (Ngai et al. 1966). Diazepam and chlordiazepoxide do not significantly alter monosynaptic reflexes. Pentobarbital, cyclopropane, and nitrous oxide reduce monosynaptic reflexes. According to Ngai et al., these findings suggest that central depressants such as diazepam, chlordiazepoxide, and some anesthetics act upon supraspinal structures (most likely the reticular facilitatory system) in blockade of spinal polysynaptic reflexes.

It has been proposed that a number of neurotransmitter systems, including acetylcholine, catecholamines, serotonin, GABA, and glycine, participate in sedative, anxiolytic, muscle-relaxant, and anticonvulsant action of benzodiazepines (Costa and Guidotti 1979). The neurotransmitter dopamine may also be affected by benzodiazepines. Experimental evidence exists that diazepam (1–10 mg/kg) administered intraperitoneally in rats decreases synthesis of dopamine in the limbic and striatal areas of the brain (Biswas and Carlsson 1978). However, most evidence shows that GABA and benzodiazepines interact and that benzodiazepines potentiate GABA-mediated inhibition in the CNS.

In vitro binding of ^{3}H-strychnine and benzodiazepines has suggested that the inhibitor amino acid transmitter glycine may also be associated in mediation of benzodiazepine action. However, in vivo studies indicate that inhibitory response to glycine is unaffected by presence of benzodiazepines. Thus the glycinergic hypothesis for benzodiazepine action can be discounted, because benzodiazepines do not preferentially antagonize convulsions induced by strychnine (Costa and Guidotti 1979).

Existence of benzodiazepine receptors and failure of a wide variety of known transmitters to inhibit diazepam binding suggest that the brain may contain an unidentified endogenous ligand. To date, purines (inosine, hypoxanthine), nicotinamide, ethyl-β-carboline-3-carboxylate, and thromboxane A_2 are likely candidates as endogenous ligand substances. However, affinity of these substances, especially the purines, for the benzodiazepine receptor is many orders of magnitude lower than that of the benzodiazepines (Tallman et al. 1980). Nicotinamide appears to be the most likely candidate from the standpoint of benzodiazepine-like neuropharmacologic profile (Möhler 1981).

It is possible that the efficacy of benzodiazepines in long-term treatment of epilepsy may be improved by concurrent administration of centrally active drugs that mimic the effect of GABA (Tallman et al. 1980). Development of such agents could also advance knowledge of the mechanism of benzodiazepine binding and activity. One such compound has already been reported to enhance benzodiazepine binding and appears to modify behavior of animals (Beer et al. 1978; Williams and Risley 1979).

CARDIOPULMONARY SYSTEM. Diazepam produces minimal effects on the cardiovascular system and has some respiratory depressant effect. A transient arterial hypotensive effect occurs in the dog following IV injection (8 mg/kg), and doses as high as 15 mg/kg injected over 3 hours decrease mean arterial pressure (Randall et al. 1961). In human patients with ischemic heart disease, there is evidence that coronary blood flow is maintained or increased following induction of anesthesia with diazepam.

In the horse, IV doses (0.05, 0.1, 0.2, and 0.4 mg/kg) of diazepam have been administered to determine their effect upon cardiopulmonary function (Muir et al. 1982). No significant changes in heart rate; cardiac output; mean pulmonary arterial, aortic, and right atrial pressures; respiratory rate; and arterial pH or blood gas values were observed. According to Muir et al., use of commercially formulated diazepam in 40% propylene glycol does not alter cardiac rate or rhythm in horses. In humans, the solvent for diazepam periodically produces arterial hypotension and arrhythmias (Greenblatt and Koch-Wesser 1973).

PHARMACOKINETICS. The major metabolite of diazepam in the dog is *N*-desmethyl-diazepam (or nordiazepam) (Jeppsson 1976). Mean plasma half-lives of diazepam and nordiazepam in the dog after an IV injection of diazepam (1.25 mg/kg) are 142 ± 17 and 171 ± 8 minutes respectively. Administered at a higher IV dose (2 mg/kg), the elimination half-life of diazepam in the dog is 3.2 hours (Löscher and Frey 1981). The major metabolite, nordiazepam, appears rapidly in the plasma of the dog and can exceed the concentration of the parent drug. Other plasma metabolites of diazepam found in the dog are oxazepam and 3-hydroxydiazepam. Nordiazepam and oxazepam metabolites are active at an equivalent order of magnitude as diazepam upon the CNS.

Oral administration of diazepam (1 or 2 mg/kg) 3 times daily maintains steady-state plasma concentrations of 1–2 μg/mL nordiazepam and maximal diazepam concentrations of 0.1–0.8 μg/mL (Löscher and Frey 1981). Concentrations of oxazepam in plasma did not exceed 0.1–0.2 μg/mL. Also, this dose regimen does not appear to induce microsomal enzyme activity.

Pharmacokinetically, diazepam and nordiazepam have been studied in the cat after IV doses of 5, 10, and 20 mg/kg diazepam and 5 and 10 mg/kg nordiazepam (Cotler et al. 1984). Distribution or α phase of diazepam is rapid, with a harmonic mean half-life of 0.35 hour; the mean elimination half-life is 5.46 hours. For nordiazepam, a harmonic mean elimination half-life of 21.3 hours was obtained; this elimination rate in the cat is 4.3 times slower than diazepam (Colter et al. 1984). About 50% of an administered dose of diazepam is metabolized to nordiazepam in the cat.

In the horse, IV infusion of 80 mg diazepam/animal (0.17–0.19 mg/kg) over 5 minutes results in a plasma elimination half-life of 6.94–21.6 hours. These data were obtained from 3 horses (Muir et al. 1982).

Nordiazepam (*N*-desmethyldiazepam) is conjugated to glucuronic acid in the horse; this conjugate is the major urinary metabolite of diazepam (Muir et al. 1982). Interestingly, no nordiazepam is detected in the plasma of the horse. Apparently, the biotransformation of diazepam and formation of the glucuronide conjugate of nordiazepam are so rapid that neither the metabolite (i.e., nordiazepam) nor its conjugate can be detected in plasma. Additionally, other metabolites (oxazepam and *N*-methyloxazepam) are detectable in urine of the horse; diazepam is not detected (Muir et al. 1982).

At a serum concentration of 75 ng/mL, serum protein binding of diazepam averages 87% in the horse (Muir et al. 1982). After IM administration of diazepam (0.17–0.19 mg/kg), plasma concentrations increase rapidly and attain maximum levels at 1.5–2 hours; thereafter, plasma concentrations decline. In horses given this IM dose regimen, bioavailability averages 93% (Muir et al. 1982). In the dog, diazepam (1 or 2 mg/kg) administered orally 3 times daily resulted in bioavailability values ranging from 74 to 100% (Löscher and Frey 1981).

SKELETAL MUSCLE. The central muscle-relaxing action of diazepam and related benzodiazepines principally affects polysynaptic reflexes at the supraspinal level (Kanto and Klotz 1982). A spinal cord depressant action at the interneuronal level, as well as an inhibitory effect upon acetylcholine release at the presynaptic level, has been proposed.

Diazepam is capable of prolongation or potentiation of the muscle-relaxing action of nondepolarizing drugs such as *d*-tubocurarine and pancuronium. However, this interaction does not appear to be clinically significant. In the dog, diazepam does not reduce or attenuate the occurrence or severity of succinylcholine-induced muscle fasciculations (Raffe et al. 1982). This action would be anticipated, since succinylcholine is a depolarizing agent at the neuromuscular junction. According to Raffe et al., use of diazepam as a pretreatment for preventing succinylcholine-induced muscle fasciculation cannot be recommended.

TERATOGENESIS AND CARCINOGENESIS. Until more is learned about possible teratogenic effects of the benzodiazepines during gestation or pregnancy, diazepam and related drugs should not be used in breeding animals. Cleft palate has been associated with maternal intake of diazepam in humans (Saxen and Saxen 1975).

Inasmuch as benzodiazepines are extensively used in humans, concern about possible adverse effects have arisen because of reports that oxazepam induces liver neoplasms in mice. Moreover, there are indications that diazepam has neoplasm-promoting activity (Horobin 1981).

In the rat, studies were conducted upon six benzodiazepine tranquilizers to determine whether or not initiation or promotion of tumors can be induced in the liver (Remandet et al. 1984). Among those studied were diazepam, oxazepam, lorazepam, and clorazepate. No evidence could be found of initiating or promoting activity of benzodiazepines for rat liver. With respect to the importance and extensive use of the benzodiazepines, additional research is necessary to explore the suggestion of some investigators of a possible neoplasm-promoting effect in other organs.

BEHAVIORAL CHANGES. In the human, maintenance of verbal contact is an advantage when benzodiazepines are used in certain diagnostic or operative procedures. In outpatients they are useful as sedative-anxiolytic and amnesic agents.

In veterinary medicine, diazepam has been used in dosages that moderately sedate animals. However, the cat does not appear to respond as well as most species; aberrant behavior is sometimes seen. In the horse, the behavioral effects become more prominent as the IV doses (0.05, 0.1, 0.2, and 0.4 mg/kg) of diazepam are increased (Muir et al. 1982); increased CNS depression and muscle relaxation occur with increasing dosages. IV doses of diazepam greater than 0.2 mg/kg produce marked muscle-relaxant action and sternal or lateral recumbency. A fixed gaze and muscle tremors of the head, neck, and thorax occur after the IV injection of 0.2 mg/kg diazepam; ataxia occurs 2 minutes after its administration in horses. Other effects after this dose is administered have been described by Muir et al. (1982): (1) One animal collapsed and was recumbent for 3 minutes; however, it regained a standing position but remained ataxic. The ataxia was manifested by weaving from side to side, leaning against the stockade, or standing with crossed rear limbs. (2) None of the horses extended or lowered their heads; they appearead to be less aware of their surroundings. Ataxia and less awareness of their surroundings lasted for about 50 minutes in 4 of 7 horses. (3) Two hours after diazepam administration, all horses were calm but appeared to have recovered to normal.

ANTICONVULSANT ACTION. The anticonvulsant properties of the benzodiazepines are useful in treatment of status epilepticus (see Chap. 16), tetanus, convulsions caused by metaldehyde toxicity, and convulsions caused by overdoses of local anesthetics. Generally, diazepam and related benzodiazepines have been recommended as first aid agents in treatment of convulsions of different origin (Kanto and Klontz 1982). However, in the adroit hands of the clinician, the rapid and anticonvulsant effect of thiopental or thiamylal must also be considered.

DRUG INTERACTIONS. Diazepam and related derivatives potentiate the action of other CNS depressants such as the phenothiazines and barbiturates. Since diazepam binds to plasma proteins extensively, its use with other known compounds that bind heavily with plasma proteins should be carefully considered.

Although benzodiazepines potentiate the action of nondepolarizing skeletal muscle relaxants, this does not appear to be clinically significant. Cimetidine, an H_2-histamine-receptor blocking agent, impairs the hepatic microsomal oxidation of diazepam; this prolongs its clearance from the body and increases its elimination half-life (Greenblatt et al. 1984).

CLINICAL USE. Although the FDA has not approved use of benzodiazepines in animals, they are being used (especially diazepam) with increasing frequency in veterinary medicine. As a class of drugs the benzodiazepines are used as behavioral modifiers, premedicants, anesthesia induction agents, and adjuvants in neuroleptanalgesia and for their anticonvulsant effects (see Chap. 16 for details on anticonvulsant action of diazepam).

Diazepam is available in injectable and oral forms. The injectable preparation contains 5 mg/mL diazepam compounded with 40% propylene glycol, 10% ethyl alcohol, 5% sodium benzoate and benzoic acid as buffers, and 1.5% benzyl alcohol for preservative purposes. Extreme caution is necessary in administering this preparation; it is necessary to inject the IV drug form slowly. Small veins should not be used. Intra-arterial administration must be avoided. Diazepam and the vehicular organic solvents can irritate blood vessels and induce pain on injection. In humans, phlebitis and thrombosis after injection of diazepam can result in the loss of a limb (Schneider and Mace 1984).

DOGS AND CATS. In the dog there is considerable individual variation in response to the sedative effects of diazepam. It produces excitation in some dogs and does not induce sedation in others (Haskins et al. 1986b). Diazepam does not have a tranquilizing effect in the healthy dog and should not be used without benefit of an adjunct sedative (Haskins et al. 1986b).

A small IV dose of diazepam will produce unconsciousness in some animals, whereas others may not be drowsy after 2 mg/kg (Hall 1976).

In general, the recommended dose of diazepam in the dog and cat is 1 mg/kg administered intravenously or orally (Kirk 1977). A maximum of 20 mg and 5 mg for a single dose is suggested as the upper limit for the dog and cat respectively. In treatment of epileptic seizures, it may be necessary to exceed these upper limits (see Chap. 16).

Diazepam (5 mg) given intramuscularly and sodium penicillin G (600,000 units every 8 hours) administered intravenously were used in treatment of a 4-month old-Brittany Spaniel afflicted with tetanus (Bodily 1979). This treatment was followed with 10 mg diazepam and 30,000 units of tetanus antitoxin in an IV drip of lactated Ringer's solution; a few hours later, methocarbamol at 45 mg/kg was given intravenously to achieve muscle relaxation. Other pharmacologic agents (pentobarbital, procaine penicillin G, phenobarbital, ampicillin, and an expectorant-antihistamine-antitussive combination) were used up to discharge from the clinic on day 10.

Diazepam (1–2 mg/kg) has been used in the dog to treat convulsive seizures resulting from metaldehyde poisoning (Turner 1973). Diazepam (0.2–0.6 mg/kg) administered intramuscularly or intravenously is considered a very effective and safe premedicant, particularly in the aged dog with cardiac disease (Muir 1977).

In the dog, IV diazepam (0.27–0.44 mg/kg) followed by IV ketamine (11 mg/kg) is used to induce anesthesia (Wright 1982). Duration of anesthesia is 5–22 minutes; recovery is characterized by 10–15 minutes of ataxia and incoordination. However, this is followed by recovery soon thereafter (Wright 1982).

In humans, the combined use of benzodiazepines with ketamine is referred to as "ataranalgesia" or "ataranesthesia." This combination prevents side effects of ketamine such as cardiovascular complications, elevation in intracranial pressure, and psychomimetic responses. However, a longer recovery period must be accepted. Under field or primitive conditions, ketamine-diazepam infusions may be an optional method of choice.

In the dog, IV diazepam (0.5 mg/kg) followed by IV ketamine (10 mg/kg) is being used for general anesthesia (Haskins et al. 1986b). Until more data are available on the safety and efficacy of this drug combination, its use should be approached cautiously.

Use of diazepam for sedative, ataractic, or neuroleptic effect in the cat is apparently of questionable value. According to Chase (1977), diazepam induces irritability and aberrant behavior to such a degree that it cannot be used in cats. Diazepam (0.05–0.4 mg/kg) has been administered by the IV, IM, and oral routes to induce eating in debilitated and anorexic cats (Macy and Gasper 1985). After IV administration, eating begins in a few seconds. Benzodiazepines may increase the appetite by enhancing the negative GABA effect upon serotonin (Morely 1980).

HORSES. Use of diazepam in combination with ketamine and xylazine hydrochloride is characterized by smooth induction of and recovery from anesthesia. Dosages of diazepam, ketamine, and xylazine are described in Chap. 12 in the section on ketamine.

It has been alleged that there has been widespread use of diazepam and reserpine for their taming effects in competitive animals such as race and show horses (Ray et al. 1978). This unauthorized use creates problems in enforcement for both racing commissions and various horse show associations. Sensitive methods for quantitation of reserpine indicate that approximately 100 pg/mL of the drug can be detected in plasma; the lower limit of detection for diazepam is approximately 2 ng/mL plasma (Ray et al. 1978).

SWINE. In the opinion of Ragan and Gillis (1975), diazepam is the tranquilizing agent of choice in swine. An IM dose of 8.5 mg/kg produces excellent sedation in about 30 minutes and reduces the dose of pentobarbital by about 50%. For neuroleptic or tranquilizing action only, the recommended IM dose of diazepam is 5.5 mg/kg. The most noticeable side effect seen about 5 minutes following administration is a moderately severe posterior ataxia. This poses no serious problem because the animals usually become recumbent about 10 minutes after injection (Ragan and Gillis 1975).

For induction of anesthesia in swine, an IV combination of diazepam (0.55 mg/kg) and ketamine (11 mg/kg) has been used by R. B. Heath (Wright 1982). Duration of anesthesia is 15–35 minutes; recovery is smooth.

MINK. Diazepam has been used in mink to prevent conditions of anxiety and aggressiveness (Sandelien 1966). In white mink of the Hedlund strain, the animals are totally deaf and are extremely restless and excitable when handled. Pure breeding of this valuable strain is extremely difficult. The females frequently refuse to mate during normal estrus and may initiate vicious and even fatal fights. In reduction of this aberrant behavior, various drugs such as sedatives, hypnotics, bromines, morphine, ethanol, barbiturates, and phenothiazines, including chlorpromazine, have been used with variable success (Sandelien 1966). Trials with diazepam administered in the feed indicate that it is possible to improve mating and to prevent the females from killing their kits during whelping. For improvement of mating, the oral dose of diazepam consists of 1 mg/animal/day for 2 successive days followed by a maintenance level of 0.66 mg/animal/day. For use of diazepam in standard dark mink during whelping, 0.66 mg/animal/day is fed for 1 month or more.

GOATS. In the goat, IM atropine (0.44 mg/kg) has been used 15 minutes preceding the IM administration of diazepam (0.88 mg/kg); this is followed 10 minutes later by an IM injection of ketamine (22 mg/kg) for induction of analgesia (Kumar et al. 1983). Duration of analgesia is more than 22 minutes; time to standing without assistance is 70.8 minutes. Administration of diazepam prolongs the period of analgesia, increases muscle relaxation, and prevents reflex movements of limbs (Kumar et al. 1983). The IM dose of atropine (0.44 mg/kg) used in this study was 10 times greater than that recommended in the dog and cat on a milligram per kilogram basis; however, it must be remembered that the goat and ruminants in general require much higher doses of atropine to induce anticholinergic effects.

As in the cat, IV administration of diazepam (0.04 mg/kg) significantly stimulates feed intake in the goat; it is increased over animals that receive only IV normal saline (Anika 1985). The effect appears to be the most prominent within the first 15 minutes after administration; it is no longer evident between 30 and 45 minutes after the injection (Anika 1985).

In the goat, Bermuda grass toxicosis or tremors are suppressed for several hours by administration of diazepam (Strain et al. 1982). An IV dose of 0.8 mg/kg suppresses the tremors at the peak of toxicosis.

CATTLE. Diazepam is being studied for its sedative and appetite-stimulating effects in cattle. It induces sedation in calves with an IV dose of 0.4 mg/kg (Mirakhur et al. 1984). Additional studies are required to demonstrate the efficacy and safety of diazepam in cattle.

LABORATORY ANIMALS. Ketamine alone and combined with diazepam or xylazine has been used in a number of common laboratory animals (Green et al. 1981). Diazepam has been used in the rabbit with a number of analgesic agents for induction of neuroleptanalgesia (Flecknell et al. 1983a). In the gerbil (*Meriones unguiculatus*), IP diazepam (5 mg/kg) plus IM ketamine (50 mg/kg) has been used for induction of anesthesia (Flecknell et al. 1983b).

EXOTIC SPECIES. IV administration of ketamine (30–40 mg/kg) and diazepam (1–1.5 mg/kg) has been successfully used in diurnal raptors representing 11 species (Redig and Duke 1976). Ketamine and atropine are mixed together and administered into the brachial vein of the bird. Birds usually become immobilized within 15 seconds and anesthesia occurs within 1 minute. Five minutes after ketamine and atropine administration, diazepam is given intravenously. Owls are more sensitive to the anesthetic combination and require lower doses (10 mg/kg) of ketamine as well as greater attention during anesthetization. The anesthesia induced permits amputation of injured wings and legs, open reduction and intramedullary pinning of fractured long bones, laparotomies, and minor procedures such as radiography and repair of lacerations (Redig and Duke 1976).

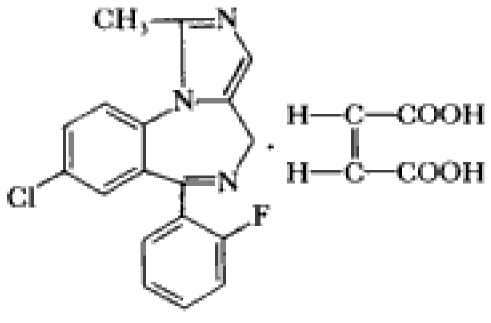
For immobilization of wild mammals, doses of diazepam vary from 1 to 3.5 mg/kg depending on species and degree of excitement at the time of IM or IV injection (Fowler 1978). Oral administration is not recommended by Fowler for chemical restraint or immobilization procedures. Onset of action is within 1–2 minutes following IV administration; after IM injection, 15–30 minutes is generally required. Clinical effects of diazepam generally are gone within 60–90 minutes (Fowler 1978).

Diazepam in combination with ketamine has been used for anesthetic purposes in river otters (see Chap. 12).

In the leopard seal (*Hydrurga leptonyx*), a combination of IM diazepam (0.2 mg/kg) and IM ketamine (1 mg/kg) has been used to induce light sedation (Gales 1984). Administration of additional doses of ketamine and diazepam are necessary to induce anesthesia.

Harbor seals (*Phoca vitulina*) and gray seals (*Halichoerus grypus*) can be immobilized by a combination of IV or IM ketamine (1.5 mg/kg) and IV or IM diazepam (0.05 mg/kg) (Geraci et al. 1981). Induction and recovery with this combination of drugs are smoother than with use of ketamine alone.

In northern elephant seal pups (*Mirounga angustirostris*) weighing 50 kg or less, IV diazepam (2.5–5 mg/animal) is generally sufficient to induce sedation (Gage 1984). Larger animals need a 0.1–0.25 mg/kg IV dose (via the intravertebral extradural vein) for sedation to facilitate force feeding. Immobilization is required in California sea lions (*Zalophus californianus*), northern elephant seals, and harbor seals for surgical diagnostic procedures; a combination of IM or IV atropine (0.02–0.04 mg/kg), IM or IV diazepam (0.22 mg/kg), and IM ketamine (4–10 mg/kg) induces anesthesia for about 15 minutes. It is suggested that atropine and diazepam be administered 5–10 minutes before administration of ketamine. The lower dose



Midazolam Maleate

Chlordiazepoxide
Hydrochloride

FIG. 14.18

given in the dose range above is suggested whenever ketamine is given intravenously. Animals may be intubated for halothane administration when procedures last more than 15 minutes (Gage 1984).

For restraint of the American alligator (*Alligator mississippiensis*), diazepam (mean dose of 0.37 mg/kg) is administered by the IM route; 20 minutes later, succinylcholine at a mean IM dose of 0.24 mg/kg is given (Spiegel et al. 1984). Muscle relaxation of the immobilized alligator facilitates examination for reproductive procedures.

Midazolam Maleate. *Midazolam Maleate,* INN (Versed), is a benzodiazepine with pharmacologic and chemical structural properties similar to those of diazepam (Fig. 14.17). It was synthesized in 1976.

Midazolam possesses all the properties characteristic of benzodiazepines. It is anxiolytic and anticonvulsant and will produce hypnosis, sedation, amnesia, and muscle relaxation. Unlike diazepam, midazolam is water soluble. High lipophilicity is reflected in the large volumes of distribution for midazolam and diazepam, although the relatively greater lipid solubility of midazolam results in a more rapid onset of action than diazepam. Midazolam is approximately 3–4 times as potent as diazepam, although relative potencies differ among the benzodiazepines with respect to each of the pharmacodynamic effects (Reves et al. 1994). The imidazole ring of midazolam is rapidly oxidized by the liver, accounting for its shorter duration of action when compared with diazepam. According to metabolism and plasma clearance, midazolam is classified as short lasting, whereas diazepam is classified as long lasting (Reves 1984; Greenblatt et al. 1981). Midazolam is biotransformed to hydroxymidazolams, which are relatively inactive metabolites (Ziegler et al. 1983).

Midazolam appears to be useful for induction of anesthesia in humans when a substitute for ultrashort-acting barbiturates is desired (Sarnquist et al. 1980). Ten mg midazolam is equivalent to 200 mg thiopental in duration of sleep induced. Apnea following IV administration of midazolam is less frequent and of shorter duration than after thiopental. In humans, midazolam appears to be a satisfactory agent for induction of anesthesia; it is about 20 times as potent as thiopental. However, it will not replace thiopental as an induction agent (Reves et al. 1985).

Midazolam cannot be used alone to maintain adequate anesthesia; nitrous oxide and halothane are effective agents for its maintenance (Reves et al. 1985). On June 1, 1986, midazolam was approved by the FDA for use in humans.

Midazolam dosages for use in veterinary patients have not been established. Suggested dosages are similar to those for diazepam: 0.045–0.1 mg/kg by IV or IM injection for the dog and cat; 0.0045–0.01 mg/kg by IV injection for the horse (Muir and Hubbell 1989).

Chlordiazepoxide Hydrochloride. Chemically, *Chlordiazepoxide Hydrochloride,* USP (Librium), is 7-chloro-2-methylamino-5-phenyl-3*H*-1,4-benzodiazepine 4-oxide monohydrochloride (Fig. 14.18). Its pharmacologic activity is comparable to that of diazepam; however, it has less overall potency. In treatment of anxiety and related conditions in humans, its long-term use is ordinarily free from most complications. Several publications report liver damage, including icterus, from long-term administration of chlordiazepoxide. In the rat, studies on the isolated perfused liver reveal that the drug decreases bile flow and biliary excretion of sulfobromophthalein (Abernathy et al. 1975). Most veterinary medical uses in animals do not extend over long periods. Development of liver impairment in animals following short-term treatment is unlikely.

In humans, data suggest the possibility that chlordiazepoxide may be teratogenic when administered during the first 6 weeks of pregnancy (Milkovich and Van Den Berg 1974). SC administration of high doses (50 and 200 mg/kg) 1 or more days prior to the time for normal palate closure in the mouse results in structural deformities (i.e., cleft palate) (Walker and Patterson 1974). Until more is learned about possible teratogenic effects of chlordiazepoxide during gestation or pregnancy, its use should be avoided in breeding animals.

Chlordiazepoxide is classified as a Schedule IV drug under the 1970 Controlled Substances Act.

TABLE 14.3—Dose of chlordiazepoxide used in zoological species

Species	Dose	Route	Effects
	(mg/kg)		
European lynx	6	Oral	Calm in 2–3 hr; drowsiness and ataxia noted for several hours
Dingo	3	Oral	Onset of action in about 2 hr; no ataxia noted; allowed petting
	7	Oral	Ataxia produced
Guinea baboon	13	Oral	Docile in 2.5 hr to allow IV pentobarbital
Sea lion	7	Oral	Lethargy and calmness noted 4 hr later
Burmese macaque	5	IM	Calmed for anesthesia
Red kangaroo	11	Oral	Calm in 1.5 hr for radiographs
Mule deer	2.2	IV	Calm within a few minutes
Gnu	4	IM	Calm in 45 min
Gerenuk	5	IM	Calm in 45 min

CLINICAL USE

SWINE. Chlordiazepoxide in an IM dose of 5–10 mg/kg has an onset of action about 1 hour following administration (Ragan and Gillis 1975). Sedative action of the drug is unpredictable; there is no advantage in its use over phenothiazine derivatives (Ragan and Gillis 1975).

EXOTIC ANIMALS. Although chlordiazepoxide produces a satisfactory effect in a number of exotic animals, it fails to produce a desired effect in the Sumatran tiger, Hensel's cat, tapir, and klipspringer (Heuschele 1961). However, the lynx and dingo are converted from hostile, aggressive animals to docile ones. Doses of chlordiazepoxide reported by Heuschele (1961) to have produced favorable responses in zoological species are summarized in Table 14.3.

Benzodiazepine Antagonists. Three different classes of benzodiazepine ligands have been identified: agonists, antagonists, and inverse agonists (Möhler and Richards 1988). The agonists alter the conformation of the $GABA_A$-receptor complex, with the resulting occurrence of the agonist effects (anxiolysis, hypnosis, anticonvulsant action, muscle relaxation). Antagonists occupy the benzodiazepine receptor but produce no activity, therefore blocking the actions of the agonists. The inverse agonists reduce the efficiency of the GABA inhibitory system, thereby resulting in CNS stimulation.

Flumazenil. In 1979, a specific benzodiazepine receptor antagonist, flumazenil (formerly R015-1788; Mazicon), was synthesized. *Flumazenil* (ethyl-8-fluoro-5,6-dihydro-5-methyl-6-oxo-4*H*-imidazo[1,5-a] benzodiazepine-3-carboxylate) (Fig. 14.19) was the first benzodiazepine antagonist approved for clinical use in human medicine (Brogden and Goa 1991). Flumazenil has high affinity and great specificity for the benzodiazepine receptor and minimal intrinsic effect (Haefely 1988; File and Pellow 1986). It is a competitive antagonist, interacting with the receptor in a concentration-dependent and reversible manner. Flumazenil is metabolized in the liver and rapidly cleared from the plasma. Compared to other benzodiazepines, flumazenil has the highest clearance and shortest elimination half-life. This results in the potential for resedation when a benzodiazepine agonist with a longer duration of action is administered (Reves et al. 1994). Similarly, agonists that are more potent than flumazenil, such as lorazepam, may require administration of additional antagonist (Dunton et al. 1988). Flumazenil has successfully reversed several benzodiazepine agonists, including midazolam and diazepam (Reves et al. 1994). Flumazenil is devoid of any inherent cardiovascular and respiratory effects but will reverse those effects of the agonists. Flumazenil has no anticonvulsant properties and will reverse the anticonvulsant properties of benzodiazepine agonists. There is evidence that flumazenil tends to reverse the hypnotic and respiratory effects more than the amnesic effects of benzodiazepine agonists (Weinbrum and Geller 1990; Ghoneim et al. 1989; Curran and Birch 1991). It will not reverse respiratory depression associated with opioid administration (Weinbrum and Geller 1990).

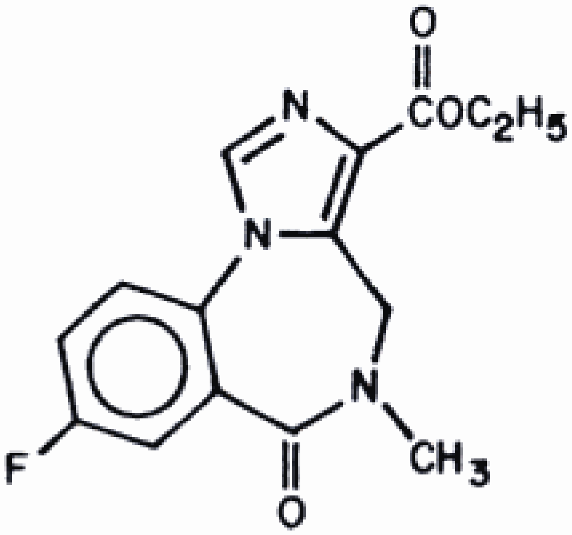

FIG. 14.19.—Flumazenil

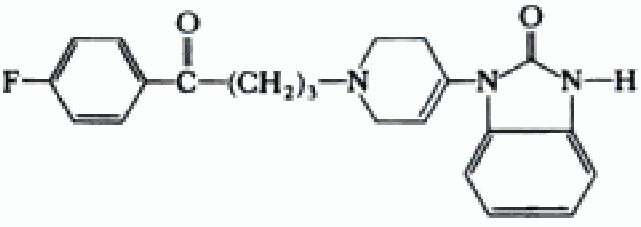
A role for flumazenil in veterinary medicine has not been established. At present, the most likely use for flumazenil will be in human medicine to treat overdose with benzodiazepines or to reverse benzodiazepine sedation associated with anesthesia (Reves et al. 1994). Flumazenil has also increased the effectiveness of a benzodiazepine derivative that has been used to treat schistosomiasis in humans. Patients become profoundly sedated when administered 3-methylclonazepam to destroy the parasite. Flumazenil prevents the sedation of the benzodiazepine but does not interfere with the antiparasitic effects, because it is ineffective at benzodiazepine binding sites in schistosomes (Möhler et al. 1981).



Droperidol

FIG. 14.20

BUTYROPHENONE DERIVATIVES

Mechanism of Action. The butyrophenones are neuroleptics similar to the phenothiazines, with the predominant effect of dopamine receptor blockade (see the section on the phenothiazine derivatives). The butyrophenones have selective affinity only for the dopamine D$_2$-receptor subfamily, whereas the phenothiazines have affinity predominantly for the D$_1$-receptor subfamily (Hyttel et al. 1985). Butyrophenones are often referred to as selective dopamine antagonists, but they also possess some affinity for 5-hydroxytryptamine (5-HT) and α$_1$ adrenoceptors. Although there is a high correlation between dopamine-receptor blockade and neuroleptic activity, it has been suggested that interaction with other receptor types may also play a part in neuroleptic effects or may be implicated in neuroleptic-associated side effects (Hyttel et al. 1985).

Droperidol. *Droperidol,* USP (Inapsine, Droleptan), also known as dehydrobenzperidol, has a complex chemical structure (Fig. 14.20). Droperidol was combined with fentanyl citrate and marketed under the proprietary name of Innovar-Vet, but the combination is no longer available (see Chap. 13). A combination of 4-AP and naloxone (0.5 mg/kg and 0.04 mg/kg respectively) administered rapidly by the IV route antagonizes the effects of droperidol-fentanyl in dogs (Booth et al. 1982). Droperidol-fentanyl-pentobarbital anesthesia in dogs is best antagonized by the IV combination of naloxone (1 mg/kg) and doxapram (5 mg/kg) (Hatch et al. 1986).

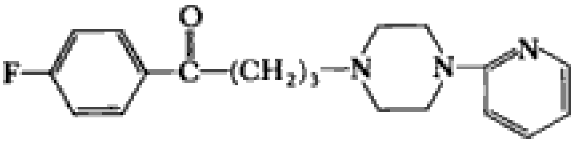
PHARMACOLOGIC CONSIDERATIONS. Droperidol is 400 times more active in dogs than chlorpromazine or chlorprothixene and 10 times more active than haloperidol. Droperidol has the shortest action of the butyrophenones. It is the most potent antiemetic known, being up to 1000 times more active than chlorpromazine and chlorprothixene. Droperidol-fentanyl in an IV dose of 1 mL/16 kg is capable of blocking the emetic effect of an IV dose of 0.04 mg/kg apomorphine in the dog (Keith et al. 1981).

As cataleptic immobility–producing drugs and inhibitors of spontaneous and conditioned learning behavior in rats, butyrophenones are several times more effective than chlorpromazine and chlorprothixene. They are also several times more effective as antagonists of amphetamine and apomorphine action in the rat than chlorpromazine and chlorprothixene. Quite unlike butyrophenones, phenothiazines are potent hypotensive and hypothermic agents as well as antagonists of epinephrine. Phenothiazines induce ataxia at much lower dosages and are quantitatively more toxic in action than butyrophenones. The wide safety margin of droperidol is related to its brief duration of action of about 2 hours. Droperidol as well as chlorprothixene may be classified among the most potent antitraumatic shock agents known. There seems to be an interrelationship between antitraumatic shock activity and ability of these agents to inhibit arterial vasoconstriction. In the dog, droperidol has a wide safety margin; tremors, muscle spasticity, and hyperirritability occur only after IV administration and at high doses (11–22 mg/kg). At an IV dose of 0.5 mg/kg, droperidol has little or no effect on cardiac output but decreases arterial pressure, total peripheral resistance, and heart rate. Adrenergic blockade is one of the principal pharmacologic actions of IV droperidol (0.125 mg/kg) in the dog. The slight hypotensive effect at this level is probably due to peripheral vasodilation caused at least in part by adrenergic blockade. IV droperidol (4 mg/kg) causes slowing of respiration and heart rate, hypotension, and a drop in cardiac output as well as a decrease in the force of myocardial contraction.

In the USA, droperidol is available as a single agent for use in humans. Its use in veterinary medicine is primarily in combination with fentanyl for neuroleptanalgesic purposes (see Chap. 13).

PRECAUTIONS AND CONTRAINDICATIONS. Since droperidol and related butyrophenones block α-adrenergic receptors, administration of epinephrine is contraindicated. In animals with severe cardiovascular disorders, the hypotensive action of droperidol may worsen the condition; cardiovascular collapse is possible. Plasma prolactin concentrations are increased by butyrophenone drugs by virtue of their blockade of dopamine receptors within the hypothalamus. Galactorrhea may occur as a side effect.

Azaperone. Azaperone (Stresnil, Suicalm) is a neuroleptic agent belonging to the butyrophenone derivatives. It has been used for nearly two decades in



Azaperone

FIG. 14.21

European countries. In October 1983, azaperone was approved by the FDA for use as a tranquilizer in swine weighing up to 36.4 kg to control aggressiveness and fighting (Porter and Slusser 1985).

Azaperone chemically is 4′-fluoro-4-[4-(2-pyridyl)-1-piperazinyl]butyrophenone (Fig. 14.21).

Azaperone is commercially available in the USA as an injectable solution containing 40 mg/mL. It should be stored at 15–30° C.

Pharmacologic Considerations. Azaperone is a relatively nontoxic, short-acting drug that is rapidly detoxified and eliminated. It is active for 2–3 hours and is nearly eliminated from body tissues within 16 hours (Callear and Van Gestel 1973). Tissue residues of azaperone accumulate in kidney, liver, brain, and skeletal muscle, ranging from less than 20 to 80 ppm 1 hour after an IM injection of 0.4 mg/kg (Rauws and Olling 1978). The metabolite of azaperone (i.e., azaperol) is also present as a tissue residue. For more information on tissue residues, see Chap. 58.

Studies have been conducted on the hemodynamic and pulmonary effects of azaperone following IM and IV administration in swine (Clarke 1969). IM doses of 0.54–3.5 mg/kg reduce arterial pressure to between 70 and 84% of control values and reflexly stimulate respiration. The severity of the drop in blood pressure appears to be related to dose level and usually occurs within 5–10 minutes after administration. The skin of the pig becomes pink, ostensibly from cutaneous vasodilation (Clarke 1969), which may be related to the blockade of α-adrenergic receptors. Such blockade by azaperone occurs in the rat, cat, and dog (Hapke and Priggs 1972). In the pig, azaperone blocks the α-adrenergic action of phenylephrine (Gregory and Wilkins 1986). Additionally, azaperone has a moderate β-adrenergic blocking action and may suppress sympathetic reflexes.

Administration of 0.03 mg/kg azaperone by the IV route in the pig results in a greater drop in arterial pressure (42% of the control value). In addition, initial violent excitement occurs, with good sedation following later. Respiration rate becomes elevated during the period of sedation, and a fall in the P_aCO_2 is observed (Clarke 1969). Other cardiovascular effects include reduction in heart rate and cardiac output.

In the pony, mean arterial pressure is lowered for at least 4 hours by IM injection of azaperone (0.4 or 0.8 mg/kg) (Lees and Serrano 1976). This is about as long as the neuroleptic action of azaperone lasts. Arterial hypotension in the early stage of drug action is due to a drop in peripheral resistance, which is similar to the pharmacologic action of droperidol. Azaperone does not alter plasma protein concentrations; the packed-cell volume and hemoglobin concentration are lowered by 5–10% for at least 4 hours in the pony. Arterial pH, P_aCO_2, and P_aO_2 remain relatively stable throughout the action of azaperone (Lees and Serrano 1976).

Azaperone prevents halothane-induced malignant hyperthermia in susceptible swine (McGrath et al. 1985). The minimal IM protective dose of azaperone that protects 100% of the pigs is 0.5 mg/kg; the minimal IM dose that produces toxicity is 10 mg/kg.

Because azaperone has a number of other pharmacologic properties similar to droperidol, see the discussion above on droperidol.

Clinical Use

SWINE. Azaperone is used in swine to prevent population stress and aggressiveness and fighting that occur upon mixing litters (Symoens and Van Den Brande 1969). It is indicated in reduction of excitement during parturition and in prevention of sows from overt mistreatment and abuse of their young. In Pietrain pigs, azaperone is used for prevention of excitement and reduction of mortality from the "overloading of the heart" syndrome common to this breed. It is used prior to minor and major surgical procedures conducted under local, regional, and general anesthesia (Jones 1972).

The efficacy of azaperone against aggressiveness in the pig has been evaluated in animals brought together in small, unfamiliar groups (Symoens and Van Den Brande 1969). After an IM dose of less than 1.5 mg/kg, piglets and adult pigs lie down in 3 and 10 minutes respectively for 30–60 minutes. Despite the influence of azaperone, violent fighting follows whenever they are startled by inadvertent noise or disturbance in an adjacent pen. Some animals treated at doses lower than 1.5 mg/kg die following episodes of fighting (Symoens and Van Den Brande 1969). When IM doses of 1.5–3 mg/kg are administered, sedation is observed within 5–15 minutes. This effect lasts about 2 hours, after which the pigs move about without difficulty and without manifesting aggressiveness. Although occasional fighting occurs to establish a pecking order, it usually is of short duration and intensity. No deaths have occurred in animals treated at these dosages (Symoens and Van Den Brande 1969). Untreated or control animals fight more than twice as frequently and four times as long.

The remarkable action of azaperone in inhibiting aggressiveness in the pig not only occurs during sedation but appears to be permanent. Perhaps by the time sedative effects have waned or disappeared, animals have adapted to each other by exchange of sensory information (smell) and acceptance of one another occurs (Symoens and Van Den Brande 1969). In contrast to these findings, Blackshaw (1981) reported that 1 mL/20 kg or 2 mg/kg of injected azaperone (probably by the IM route) does not prevent fighting. Fighting in treated groups was seen as often upon recovery from the drug as in untreated groups. The different results of these investigators are unexplained.

In a field study involving a large number of pigs, azaperone use has been classified according to type of effect following IM administration (Callear and Van Gestel 1973): (1) low doses (0.4–1.2 mg/kg) for stress conditions such as anxiety and nervousness permit animals to remain ambulatory and calm; (2) median doses primarily for the socializing effect at a level of 2 mg/kg cause animals to eventually lie down and appear somnolent but allow them to move around if disturbed; and (3) when high doses of 4 mg/kg in adult pigs and 8 mg/kg in piglets are given for their knock-down effect for minor surgical procedures, animals become recumbent and are unable to stand.

To avoid untoward effects, it is recommended that 2 mg/kg not be exceeded in large boars (Callear and Van Gestel 1973).

Recommendations of the European manufacturers for use of azaperone in the pig intramuscularly are 1 mg/kg for production of sedation, 2.5 mg/kg for reduction of aggressiveness, and 5–10 mg/kg for knock-down or immobilization effect (Cox 1973). In the USA, an IM dose of azaperone (2.2 mg/kg) in the feeder pig is approved by the FDA.

Azaperone must be administered by the IM route or it will be ineffective. It must be given by deep IM injection either behind the ear and perpendicularly to the skin or in the gluteal region; injection into or near the sciatic nerve must be avoided. A disadvantage of azaperone for immobilization of adult swine is the large volume that must be administered.

According to Blackshaw (1981), azaperone does not reduce the aggressive interactions between pigs at weaning nor does it provide an added growth or weight gain advantage in the period after weaning. Moreover, Blackshaw stated that there appears to be no economic or commercial advantage to injecting azaperone into pigs placed together at weaning.

In boars, IM azaperone (1.5 mg/kg) reduces fighting but does not eliminate aggressive behavior (Pasco 1986). It is suggested that azaperone may be of value in transporting boars in close confinement for no more than 4 hours if they have been detusked.

Azaperone and a hypnotic drug, *Metomidate*, INN (Hypnodil), are used in combination to produce a condition resembling neuroleptanalgesia in the pig. Azaperone is given in an IM dose of 2 mg/kg and is immediately followed by metomidate intraperitoneally at 10 mg/kg (Cox 1973). As an alternative, azaperone (2.5 mg/kg) is given intramuscularly, and 20–30 minutes later metomidate (2.5 mg/kg) is administered intravenously (Jones 1972). This combination produces deep sedation for over 1 hour and is satisfactory for surgical procedures such as amputation of a digit or cesarean section in conjunction with regional or local anesthesia. If it is necessary to extend or increase the period of sedation, another dose of metomidate (1 mg/kg) may be administered intravenously. When general anesthesia is required, and to enable endotracheal intubation, 5 mg/kg metomidate are recommended following administration of azaperone (Jones 1972). Metomidate is a nonbarbiturate agent and is used in other species (see Chap. 12).

HORSES. Azaperone is an excellent ataractic agent in the horse (Hillidge et al. 1977; Mackenzie and Snow 1977). IV administration should be avoided because it can induce marked arterial hypotension. Azaperone (0.29–0.57 mg/kg) quite frequently evokes excitement or a panic reaction following IV administration (Dodman and Waterman 1979).

The sedative effect of 0.8 mg/kg azaperone is considered to be greater than that produced by 0.1 mg/kg acepromazine when administered intramuscularly. If azaperone is used prior to induction of anesthesia with thiopental, it is suggested that IV thiopental not exceed 7 mg/kg (Hillidge et al. 1977). Generally, the cardiovascular actions of azaperone are likely to have little effect in normal animals; however, caution needs to be taken when azaperone is administered to anemic, hypovolemic, or debilitated animals.

In the pony, an IM dose of 0.4 mg/kg azaperone induces a slight to excellent degree of neurolepsy (Lees and Serrano 1976). Following a higher dose (0.8 mg/kg), a good to excellent effect is obtained. Onset of action is generally seen within 10 minutes, reaching a peak after 10–70 minutes. Effects of azaperone in the pony decrease by 2 hours and usually disappear after 4 hours.

Limited studies with azaperone-metomidate have been conducted in the horse (Hillidge et al. 1973). Azaperone has been used in an IV dose of 0.2 mg/kg followed by IV metomidate (3.5 mg/kg); surgical anesthesia lasts 8 ± 3 minutes; the approximate time required to stand takes 35 ± 25 minutes (Crispin 1984).

Hemolysis occurs in samples of venous plasma collected between 5 minutes and 6 hours following administration of azaperone-metomidate. Until more information is gained about the hemolytic effect, this drug combination should not be used in the horse (Archer 1973).

Precautions and contraindications in the use of azaperone are generally the same as those discussed for droperidol in this chapter.

    - Ropivacaine Hydrochloride

Local anesthetics are drugs that when applied locally to nerve tissue (endings or fibers) cause reversible blockade of nerve impulse conduction. At effective concentrations, local anesthetics block transmission of autonomic, somatic sensory, and somatic motor impulses. Thus, depending upon the nerve and the area innervated, autonomic nervous system blockade, anesthesia, and/or skeletal muscle paralysis may result. The action of local anesthetics is reversible. Recovery of nerve conduction occurs spontaneously without evidence of structural damage to nerve cells or fibers. This is in contrast to other compounds such as phenol that will also block neural conduction. However, in this case the action is irreversible because phenol causes cellular destruction.

HISTORY. The first clinically significant local anesthetic to be used was cocaine hydrochloride. It is an alkaloid and was first obtained from the leaves of *Erythroxylon coca,* a tree indigenous to Chile, Peru, and Bolivia. The native runners of this area chewed coca leaves to allay hunger and fatigue and produce psychic stimulation while they carried messages through the forests. The tree is cultivated now in several tropical countries. It was imported to Europe as a botanical curiosity. In 1860 Niemann isolated alkaloidal cocaine from leaves of the tree. The local anesthetic effect of the alkaloid was noted but not utilized until Koller used cocaine to anesthetize the eye in 1884. Thereafter, cocaine was accepted as a local anesthetic. It was used in dental and surgical procedures by the methods of infiltration and nerve blocking. In 1885 Corning injected cocaine intrathecally (into the subarachnoid space) in a dog and paralyzed posterior spinal nerves to produce spinal anesthesia. It was nearly 15 years later before the technique was successfully employed on humans. Also in 1885 McLean, a veterinarian of Meadville, Pennsylvania, first successfully used cocaine for nerve blocks of the limbs in the horse.

Willstatter completed the chemical structure and final synthesis of cocaine in 1902. It became apparent that cocaine possessed at least two undesirable properties, viz., a marked toxicity and drug addiction. Chemists began searching for substitutes that possessed the same local anesthetic properties. Three years later, Einhorn synthesized procaine hydrochloride. Many other compounds have been synthesized since then for use as local anesthetics. While they differ little in therapeutic efficacy, none is entirely free from undesirable properties.

The search for new and better local anesthetics continues. There are presently about 50 local anesthetic compounds of recognized clinical value. Only those of primary importance in veterinary medicine in North America will be covered here.

Requirements of an Ideal Local Anesthetic. The ideal local anesthetic should provide reversible sensory nerve blockade with no local (e.g., neural) or systemic (e.g., central nervous system [CNS] or cardiac) toxicity. The onset and duration of blockade should be predictable and consistent in all applications. As this ideal agent is not currently available, appropriate clinical selection of a local anesthetic agent must be based on an understanding of the physiology of neural conduction and the pharmacokinetics and pharmacodynamics of each individual drug.

GENERAL PROPERTIES

Chemical Structure. The typical local anesthetic molecule consists of an unsaturated aromatic group (usually a benzine ring) linked by an intermediate chain to a tertiary amine end (Fig. 15.1). The tertiary amine is a base (proton acceptor). The clinically important local anesthetics are divided into two distinct chemical groups based on their intermediate chain. The aminoesters are local anesthetics with an ester link between the aromatic and amine ends; procaine, chloroprocaine, and tetracaine are examples. Aminoamides are local anesthetics with an amide link between the aromatic and amine ends; lidocaine, mepivacaine, bupivacaine, and ropivacaine are examples (Fig. 15.2). *(Note:* a memory aid for differentiating modern, clinically important local anesthetics into the ester or the amide grouping is that [except for piperacaine, an ester not discussed in this review] amides have an "i" in the prefix [before "caine"] of the generic name of the anesthetic.)

Physicochemical Properties and Structure-Activity Relations

LIPOPHILIC-HYDROPHILIC BALANCE. The aromatic ring system and alkyl substitution to either the aromatic region or amine end of the basic local anesthetic molecule impart lipophilic characteristics to the molecule. The lipophilic nature of the molecule affects the tendency of a compound to associate with membrane lipids (lipid solubility, or hydrophobicity). Lipid solubility is related to anesthetic potency; the more lipid soluble, the greater the potency. Duration of action also increases with increased lipophilicity. For example, etidocaine has more carbon atoms on the amine end of the molecule than lidocaine and is four times more potent and has a longer duration of action (Fig. 15.2, Table 15.1). The dominance of aromatic ring substitution (over the amine substitution) in determination of lipophilicity is exemplified by comparing the actions of the two ester local anesthetics procaine and tetracaine. Although procaine has a greater amine substitution than tetracaine, the latter has a greater aromatic substitution (butyl) and is more potent and reported to have a longer clinical duration of action than procaine.

HYDROGEN ION CONCENTRATION. Local anesthetics are weak bases. In solution, local anesthetics exist in chemical equilibrium between the uncharged base (the un-ionized form) and the cationic (the ionized) form. The relative proportion of these two forms is determined by the chemical nature of the compound (salt of acid or base), the pK_a (pH at which the concentrations of the ionized and un-ionized forms are equal) of the compound, and the pH of the environment into which the solution is injected. This relationship is described by the following modified version of the Henderson-Hasselbach equation:

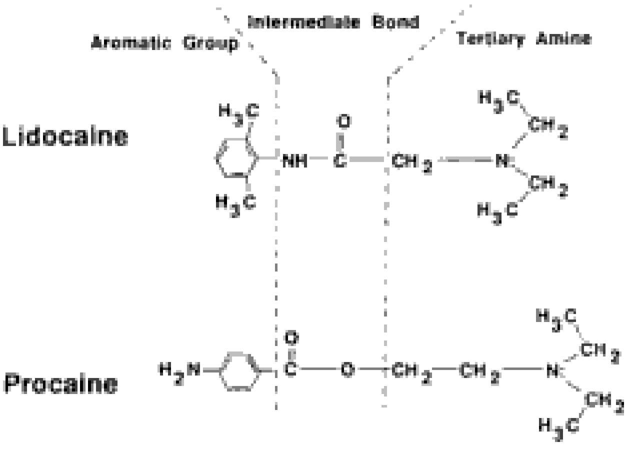

FIG. 15.1—Local anesthetics consist of hydrophilic and lipophilic (hydrophobic) ends connected by a hydrocarbon chain. The connecting chain is either an amide, as in lidocaine, or an ester, as in procaine. (From Strichartz and Berde 1994, reprinted with permission.)

$$\log\left(\frac{\text{ionized form}}{\text{un-ionized form}}\right) = pK_a - pH$$

Since local anesthetics are weak bases with pK_a values in the range of 7.5-9, the predominant form at physiologic pH is the ionized, or cationic, form (Table 15.1). While the cationic form is felt to be important for local anesthetic activity at the receptor site, it is the uncharged base that is especially important in the rapid penetration and diffusion through biological membranes (the local anesthetic receptor is likely not accessible from the external side of the cell membrane). Thus the amount in the base form strongly influences the onset of drug action and the drug's potency.

PROTEIN BINDING. The tertiary amine is relatively hydrophilic and bears some positive charge in the physiologic pH range. The degree of ionization has been positively correlated to protein binding. In general, the degree to which local anesthetics bind to proteins influences their duration of action; greater binding relates to prolonged duration of action. As discussed below, the conduction block caused by local anesthetics is believed to occur following interaction of the anesthetic with a protein receptor located within the sodium channel of the nerve membrane. If the agent has a greater affinity for the receptor and binds

Generic[a] and Common Proprietary Name	Chemical Structure	Approximate Year of Initial Clinical Use	Main Anesthetic Utility	Representative Commercial Preparation
Cocaine		1884	Topical	Bulk powder
Benzocaine (Americaine)		1900	Topical Topical	20% ointment 20% aerosol
Procaine (Novocain)		1905	Infiltration Spinal	10 & 20 mg/ml solutions 100 mg/ml solution
Tetracaine (Pontocaine)		1930	Spinal Spinal	Niphanoid crystals — 20 mg/ml 10 mg/ml solutions
Lidocaine (Xylocaine)		1944	Infiltration Peripheral nerve blocks Epidural Spinal Topical Topical	5 & 10 mg/ml solutions 10, 15, & 20 mg/ml solutions 10, 15, & 20 mg/ml solutions 50 mg/ml solution 2.0% jelly, viscous 2.5%, 5.0% ointment
Chloroprocaine (Nesacaine)		1955	Infiltration Peripheral nerve blockade Epidural	10 mg/ml solution 10 & 20 mg/ml solutions 20 & 30 mg/ml solutions
Mepivacaine (Carbocaine)		1957	Infiltration Peripheral nerve blockade Epidural	10 mg/ml solution 10 & 20 mg/ml solutions 10, 15, & 20 mg/ml solutions
Prilocaine (Citanest)		1960	Infiltration Peripheral nerve blockade Epidural	10 & 20 mg/ml solutions 10, 20, & 30 mg/ml solutions 10, 20, & 30 mg/ml solutions
Bupivacaine (Marcaine)		1963	Infiltration Peripheral nerve blockade Epidural Spinal	2.5 mg/ml solutions 2.5 & 5 mg/ml solutions 2.5, 5, & 7.5 mg/ml solutions 5 & 7.5 mg/ml solutions
Etidocaine (Duranest)		1972	Infiltration Peripheral nerve blockade Epidural	2.5 & 5 mg/ml solutions 5 & 10 mg/ml solutions 5 & 10 mg/ml solutions
Ropivacaine (Naropin)		1990	Infiltration Peripheral nerve blockade Epidural Spinal	2 & 5 mg/ml solutions 2.5 & 7.5 mg/ml solutions 5, 7.5, & 10 mg/ml solutions 7.5 & 10 mg/ml solutions

*Blocking potency relative to procaine; data from isolated nerve studies (Strichartz and Berde 1994, Table 15-2).

more firmly to the receptor site, it presumably will remain within the channel for a longer period of time, and this condition will result in a more prolonged block. This explanation remains speculative since most of the information on local anesthetic protein binding has been obtained from studies of plasma protein binding. It is assumed that a relationship exists between plasma protein binding and the degree of local anesthetic binding to membrane proteins. Bupivacaine, etidocaine, and ropivacaine are examples of local anesthetic agents that are highly protein bound and have a longer duration of action than their amide or ester counterparts (Table 15.1).

It is important to remember that the action of local anesthetics relates in large part to their chemical and physical properties and that these have largely been determined in vitro. However, in vivo the actions of these agents may be markedly altered by other circumstances; some of these will be reviewed briefly later in this chapter.

PHARMACOKINETICS. Local anesthetic agents are usually injected into a localized area of the body to block specific nerves. The absorption of the drug from the site of injection, the drug's distribution kinetics, and the degree of biotransformation and excretion of drug and breakdown products from the body are of primary importance in determining the systemic disposition of the drug and potential for toxicity (side effects).

Absorption. The systemic absorption of local anesthetic agents is influenced by many factors, including the dosage (volume and concentration), site of injection, presence of a vasoconstrictor, and physicochemical and pharmacologic properties of the drug. Many of these factors also influence duration of effect of the drug at the site of action.

In general, while the effect on systemic absorption of varying either volume or concentration (at a constant dose) of local anesthetic administered is variable and generally not significant, the overall dose is correlated with increased systemic absorption and higher peak drug levels. Site of injection also significantly influences the peak drug concentrations in the blood. Local anesthetic deposited in a highly vascular area will be absorbed more rapidly and result in higher blood levels of drug than if injected into tissue of less blood flow.

The presence of vasoconstrictor substances such as epinephrine tends to reduce systemic absorption by reducing local blood flow. But this effect may vary somewhat depending on the nature of the local anesthetic. For example, compared to use of a local anesthetic alone, concurrent use of a vasoconstrictor such as epinephrine (e.g., at concentrations of 1:200,000) reduces the peak blood levels of the shorter acting drugs (e.g., lidocaine) but has a less pronounced effect on the more lipophilic and longer acting agents (e.g., etidocaine).

Distribution. Amide local anesthetic agents are widely distributed in the body following an intravenous bolus injection; a two- or three-compartment model (Table 15.2) usually describes their pharmacokinetic properties. Distribution of ester anesthetics in tissues is much more limited because their plasma half-lives are very short (within a few minutes) due to their rapid breakdown by plasma pseudocholinesterase.

Distribution of especially amide-type local anesthetics may be further influenced by anatomic and pathophysiologic factors. For example, the lung is capable of extracting at least some amide local anesthetics and thereby limits the amount of drug reaching the systemic circulation and downstream sensitive sites (Tucker 1986). Conversely, hypercapnia and resulting acidosis in the CNS will likely increase regional blood flow and as a result increase local anesthetic concentrations in the brain and increase the risk of toxicity.

Protein binding is another factor that may influence plasma drug concentrations, as it influences the free

Table 15.2—Pharmacokinetic properties in humans of selected amide local anesthetics

Agent	$t_{1/2\alpha}$ (min)	$t_{1/2\beta}$ (min)	$t_{1/2\gamma}$ (h)	Vd_{ss} (L)	Cl (L/min)
Prilocaine	0.5	5.0	1.5	261	2.84
Lidocaine	1.0	9.6	1.6	91	0.95

drug available for both activity and clearance by the liver. Toxic plasma concentration is inversely proportional to degree of protein binding.

Biotransformation and Excretion. A major difference between the aminoamides and aminoesters is the pattern of metabolism. The esters are hydrolyzed primarily by plasma pseudocholinesterase, whereas the amides largely undergo enzymatic degradation in the liver. The difference in metabolism has implications for both clinical usefulness and observed toxicity for the two classes of compounds.

The principal metabolic pathway of local anesthetics with ester linkages is enzymatic hydrolysis. Derivatives of 4-amino-benzoic acid are primarily hydrolyzed in the plasma by nonspecific pseudocholinesterases. Cocaine is an atypical ester in that it undergoes significant hepatic metabolism and urinary excretion. The rate of plasma hydrolysis for the other ester compounds varies; chloroprocaine has the most rapid rate, followed by procaine, and tetracaine has the slowest. Toxicity is inversely related to the rate of hydrolysis.

Pregnancy, which reduces plasma cholinesterase activity, might prolong the clearance of the ester anesthetics and increase the potential for toxicity. Despite generally rapid systemic clearance of the ester anesthetics, subarachnoid administration of these drugs will result in a clinical effect until the drug is systemically absorbed. This is likely due to the lack of significant pseudocholinesterase activity in the cerebrospinal fluid. Products of hydrolysis either can be directly excreted (e.g., nearly 25% of diethylaminoethanol from degradation of procaine) by the kidney or, more commonly, can undergo metabolic transformation (Kolwas 1979). Para-aminobenzoic acid (PABA) is a breakdown product of the esters responsible for allergic reactions in some human patients.

Compared with the ester local anesthetics, the metabolism of the amide local anesthetics is more complex. Metabolism takes place primarily in the liver, although some plasma hydrolysis is thought to occur. Plasma hydrolysis may contribute to the rate of clearance of the different amide agents from the blood; prilocaine, etidocaine, and to a lesser extent lidocaine are all thought to undergo plasma hydrolysis. The amide bonds of mepivacaine and bupivacaine do not undergo hydrolysis by plasma esterases.

A common pathway in biotransformation of amide local anesthetics is dealkylation (Kolwas 1979). This chemical process involves alkyl groups either linked to nitrogen or oxygen atoms of the local anesthetic or in its products of hydrolysis. Dealkylation occurs primarily within the hepatic microsomes. Lidocaine, which has been studied extensively in human beings, undergoes oxidative *N*-dealkylation to monoethylglycinexylidide. This intermediate compound is then hydrolyzed to 4-hydroxy-2,6-xylidine, which is excreted in the urine.

Bupivacaine also undergoes hepatic dealkylation and hydrolysis but is thought to be at least partially detoxified by conjugation with glucuronic acid. This may be of clinical significance in cats since they have a limited ability to form glucuronide conjugates. The clearance of mepivacaine is reduced in neonates, which is likely due to immature enzyme system development, and hence is not recommended for use during cesarean section. Prilocaine is metabolized to ortho-toluidine, which is capable of oxidizing hemoglobin to methemoglobin, thereby limiting its clinical application.

In general, the order of clearance of amides is prilocaine (most rapid) > etidocaine > lidocaine > mepivacaine/ropivacaine > bupivacaine (least rapid). Since the amides undergo primary enzymatic degradation in the liver, changes in hepatic function and/or hepatic blood flow (as may be induced with hypotension during regional or general anesthesia and in certain disease states) will prolong the clearance of the drugs from the body and may increase the potential for side effects.

Similarly, changes in renal function might also influence clearance of local anesthetic metabolites (and to a far lesser extent the unaltered parent drugs), as they are eliminated almost entirely by the kidney. In general, because most local anesthetics contain alkaline amino radicals, excretion in an acid urine is greater because of increased ionization. In alkaline urine, renal elimination of local anesthetics is delayed or slower because the drug remains principally in the un-ionized state and may be easily reabsorbed.

PHARMACODYNAMICS

Mechanism of Action

PERIPHERAL NERVE ANATOMY. Nerve fibers are classified based on their size and myelination and have specific associated functions (Table 15.3). A typical peripheral nerve consists of individual nerve fibers, or axons, grouped together as fascicles within an outer sheath. Each of these layers has an associated connective tissue covering: axon, endoneurium; fascicle, perineurium; entire nerve, epineurium.

Peripheral nerves may be myelinated or nonmyelinated. Schwann cells form multiple myelin layers around each axon of myelinated nerves and only a single membrane layer around nonmyelinated axonal

TABLE 15.3—Nerve fibers and their susceptibility to block by local anesthetics

Fiber type	Fiber diameter (µm)	Myelination	Function	Sensitivity to block
Type A				
Alpha	12–20	Heavy	Proprioception and motor	+
Beta	5–12	Heavy	Touch and pressure	++
Gamma	3–6	Heavy	Muscle	++
Delta	2–5	Heavy	Pain and temperature	+++
Type B	<3	Light	Preganglionic autonomic	++++
Type C

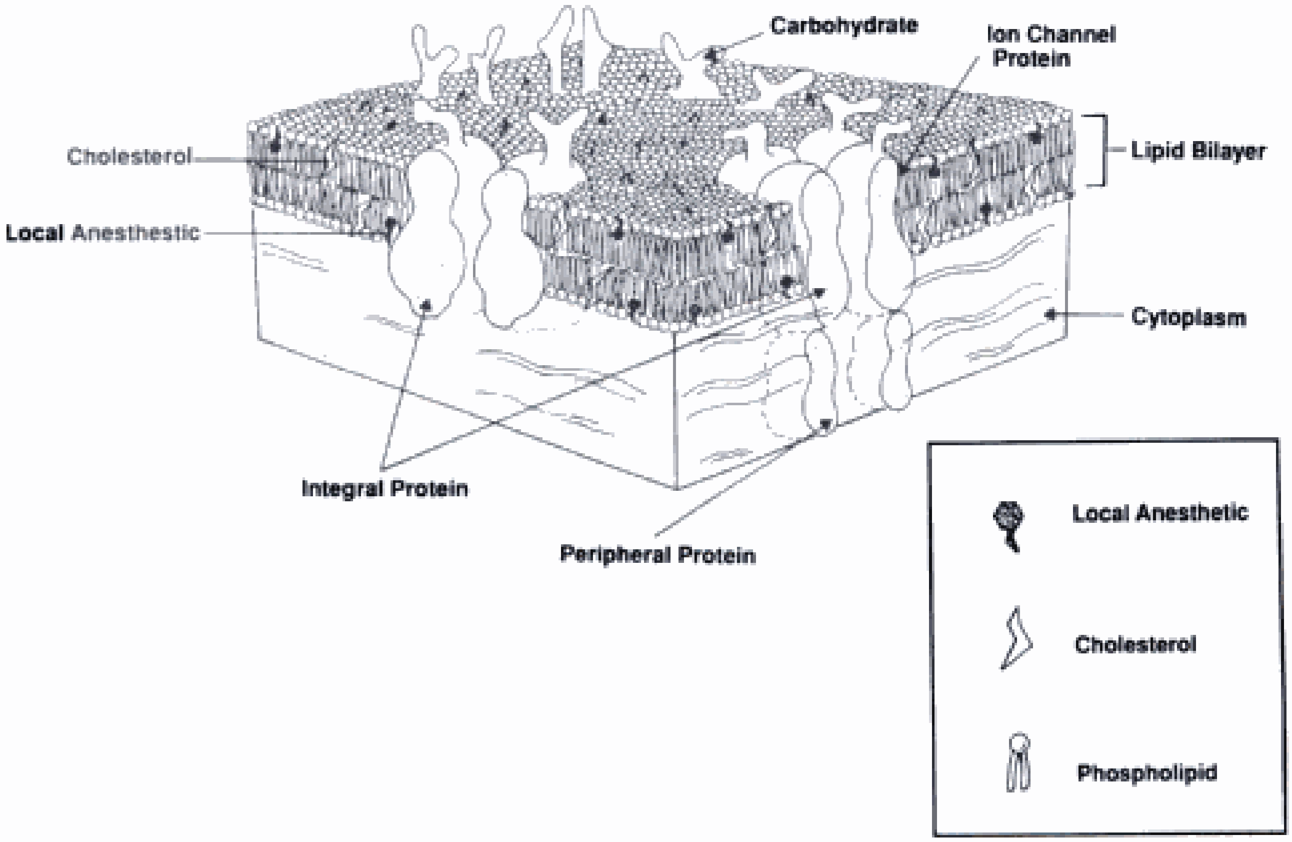

FIG. 15.3—Drawing of a typical plasma membrane showing the lipid bilayer. Probable sites for local anesthetic action are also shown. (From Strichartz and Berde 1994, reprinted with permission.)

fibers. In nonmyelinated nerves ion channels supporting propagation of the action potential are distributed all along the axon. This is in contrast to myelinated nerves, where these ion channels are concentrated at the nodes of Ranvier, which are periodic interruptions in the myelin sheath.

The axonal membrane structure is similar to that of other biologic membranes and consists of a phospholipid bilayer containing both surface and embedded proteins and carbohydrates (Fig. 15.3).

PHYSIOLOGY OF NERVE CONDUCTION AND ANESTHETIC ACTION. Local anesthetics inhibit the generation and propagation (conduction) of nerve impulses by blockage of voltage-gated sodium channels in the nerve membrane. Nerve signals are conducted by action potentials, which are rapid changes in the electrical gradients across the nerve membrane. Each action potential begins with a sudden change from the normal resting negative potential (of about −90 mV) to a positive membrane potential and then ends with a rapid shift back again to the negative potential. The action potential moves along the unmyelinated nerve fiber (conduction of the impulse) until it reaches the fiber's end. In myelinated nerves the impulse jumps from one node of Ranvier to the next (saltatory conduction). Repolarization resets the nerve membrane potential to resting conditions until it is again depolarized.

Depolarization is due to the rapid inward passage of sodium ions from the extracellular to the intracellular space via sodium channels in the membrane. Toward the end of the depolarization phase, sodium channels close and become inactivated. At the same time potassium channels slowly (compared to the sodium channels) open and allow potassium to exit from the cell. The outward flow of potassium repolarizes the membrane toward the potassium equilibrium potential (about −95 mV). The sodium channels are also returned to the resting state. At completion of this action potential, the transmembrane ionic equilibrium is reestablished by the membrane sodium-potassium pump (Guyton and Hall 1996).

Current knowledge indicates that the sodium ion channel in the nerve membrane (Fig. 15.3) is the site of action for local anesthetics. The most prominent hypothesis is that the anesthetic enters the lipoprotein membrane and binds to a receptor site in the sodium channel to impede or prevent sodium ion movement. Sodium-generated currents are reduced because the drug inhibits channel conformational changes, and thus drug-bound channels fail to open. This slows the rate of depolarization of the membrane, preventing attainment of the membrane's threshold potential. Thus, an action potential is not propagated. To a lesser extent movement through the channel is prevented also because of the bound drug's physical blockade of the ion-conducting pore. A sodium channel that is inhibited by a local anesthetic is functionally similar to an inactivated channel. If the sodium movement is blocked over a critical length of the nerve, propagation across the blocked area is not possible. The blockade of sodium channels by most local anesthetics is both voltage- and time- or frequency-dependent. For example, a higher frequency of stimulation (and depolarization) and more positive membrane potential (prolonged depolarization) facilitate a greater degree of anesthetic block. Clinically important rates of onset and duration of anesthetic block are related to the relatively slow diffusion of an agent to sites of action rather than to its faster binding to ion channels (Butterworth and Strichartz 1990; Strichartz and Berde 1994; Catterall and Mackie 1996).

DIFFERENTIAL NERVE BLOCK. Local anesthetics are capable of blocking all nerves; hence their action is not limited to the usually more desirable loss of sensation; motor loss also occurs. Nerve fibers differ substantially in their susceptibility to local anesthetic blockade due to size and presence or absence of myelination. In general the smaller fibers with higher firing rates and less distance over which such fibers can passively propagate an impulse (type B and C fibers) are blocked before larger (type A) fibers. Myelinated fibers are blocked before unmyelinated fibers of the same diameter. Thus, autonomic fibers, small unmyelinated C fibers (mediating pain sensations), and small myelinated Aδ fibers (also mediating pain and other sensations) are blocked before larger myelinated A (γ, β, α; in order of ease of block) fibers (Table 15.3). Preferential blockade also results from the state-dependent mechanism of action of local anesthetics noted above (i.e., many sensory fibers have a high firing rate and long action potential duration).

All things considered and with an eye toward practical application, a generalized (variation among individuals is large) summary of the disappearance of nervous function in response to local anesthetic blockade, in order of first to last, is as follows: pain, warmth, touch, deep pressure, and finally motor function. Such variation in neural sensitivity to local anesthetics has thus made it possible to clinically block sensory transmission in patients without also causing motor paralysis.

Anatomic considerations contribute exceptions to the size- and myelination-related blockade story. For example, in large peripheral nerve trunks, motor nerves are more circumferentially located and hence are exposed to the local anesthetic agent first. Therefore, motor blockade in this circumstance might occur prior to sensory blockade. It is also important to remember that in general the mantle of the peripheral nerve trunk contains sensory innervation to the proximal aspect of an extremity while the core contains distal sensory innervation. Hence anesthesia will develop proximally prior to distal areas becoming desensitized.

Toxicity and Complications. Local anesthetic agents are relatively free of harmful side effects when administered at an appropriate dose. Most harmful or potentially harmful reactions occur after accidental intravenous (IV) administration. However, since vascular absorption occurs, reactions may also follow regional administration of large amounts of anesthetic, especially in debilitated patients.

Side effects of local anesthetic agents are local and systemic in origin (Table 15.4). Systemic toxicity is due to elevated plasma concentration of local anesthetic, most specifically the free, or unbound, portion. The most prominent and potentially damaging systemic effects are those involving the CNS and cardiovascular system. Animal studies indicate that in general lower blood levels are required to cause CNS toxicity than to cause cardiovascular reactions. However, adverse effects involving the cardiovascular system tend to be more life threatening and difficult to manage than CNS effects.

SYSTEMIC TOXICITY

CENTRAL NERVOUS SYSTEM. Low systemic doses of local anesthetic administered to awake, unmedicated

humans are reported to cause numbness of the tongue and oral cavity. Low systemic doses will also likely contribute to reduced anesthetic requirement during general anesthesia (DiFazio et al. 1976; Himes et al. 1977, 1979; Doherty and Frazier 1998). As plasma concentration increases, local anesthetics produce a predictable pattern of CNS excitement and then depression that may be accompanied by apnea and cardiovascular collapse. Initially, humans report restlessness and difficulty in focusing their eyes. As plasma levels increase further, slurred speech and skeletal muscle twitching (usually initially in the face and limbs) occur, which precede the onset of tonic-clonic seizures. Still further increases in plasma levels result in CNS depression, unconsciousness, and respiratory arrest (Scott 1986). If a sufficiently large dose or rapid injection of local anesthetic is given, brief mild signs of CNS excitation followed rapidly by generalized depression occur. If other CNS depressant drugs (e.g., barbiturates, benzodiazepines, inhalation anesthetics) are administered in conjunction with the local anesthetic, a preceding excitatory phase is usually not seen. CNS excitation has long been believed to be the result of a local anesthetic drug block of inhibitory pathways in the cerebral cortex (Wagman et al. 1967).

Plasma concentrations producing the various phases of overdose are drug-related (and perhaps species-related). For example, in cats, procaine is least potent in terms of CNS effects (convulsions at about 35 mg/kg), and bupivacaine is one of the most potent (convulsions beginning at about 5 mg/kg) (Englesson 1974). In dogs, the relative CNS toxicity of bupivacaine, etidocaine, and lidocaine is 4:2:1 (Liu et al. 1983). There is an inverse relationship between the arterial carbon dioxide partial pressure (and arterial pH) and seizure thresholds of local anesthetics. This may reflect increases in cerebral blood flow (which in turn increases the amount of drug delivered to the brain) and/or decreases in plasma protein binding of local anesthetics (Englesson 1974; Burney et al. 1978).

CARDIOVASCULAR SYSTEM. Local anesthetics can produce direct effects on both the heart and peripheral vascular smooth muscle and indirect effects via influence on autonomic nervous activity. Direct effects on the heart may be both electrophysiological (decrease in the rate of depolarization and bradycardia and other cardiac dysrhythmias) and mechanical (decrease in myocardial contractility). Both effects on the heart result in a decrease in cardiac output. Evidence indicates that the more potent the drug as a local anesthetic, the greater the ability of the agent to decrease contractility (Stewart et al. 1963). Bupivacaine and etidocaine may produce severe cardiac dysrhythmias, including ventricular fibrillation (Tanz et al. 1984; Kotelko et al. 1984; Bruelle et al. 1996).

The effect of local anesthetics on peripheral vascular smooth muscle may be biphasic. In low concentrations constriction may occur. The more usual clinical response, especially with increasing concentrations, is relaxation resulting in vasodilation. Both the vasodilation and decrease in cardiac output result in arterial hypotension. The pulmonary circulation may be especially sensitive to the stimulatory effects of local anesthetics, and both ester and amide agents can cause marked increases in pulmonary artery resistance and hypertension (Strichartz and Berde 1994). When administered via the epidural or intrathecal route, cardiovascular collapse may be further exacerbated by sympathetic nervous system blockade as the agent spreads cranially. See also the review of Reiz and Nath (1986) for additional, more in-depth information.

LOCAL TISSUE TOXICITY

NEURAL TOXICITY. Local anesthetics are rarely neurotoxic at clinically administered concentrations. However, irreversible conduction blockade in isolated nerves has been produced with high concentrations of these agents (Strichartz and Berde 1994). Occasional prolonged sensory and motor deficits have also been reported following epidural or subarachnoid administration of chloroprocaine. This is now believed to be related to the antioxidant sodium bisulfite and not to the parent drug itself.

SKELETAL MUSCLE TOXICITY. When properly used, local anesthetics rarely produce localized tissue damage. However, there are reports that even at clinical doses for local infiltration, there may be skeletal muscle damage (Basson and Carlson 1980). This effect is more commonly seen with the longer acting agents, and the effect is generally felt to be reversible. In higher concentrations local anesthetics may be more generally histotoxic (Benoit and Belt 1970, 1972; Carlson 1976; Hall-Craggs and Singh-Seyen 1975; Libelius et al. 1970; Vasseur et al. 1984).

OTHER EFFECTS

METHEMOGLOBINEMIA. Methemoglobinemia has been reported as developing following exposure to a number of local anesthetics (Lund and Cwik 1965; Paddleford et al. 1985; Ferraro et al. 1988; Davis et al. 1993), most notably prilocaine. A dose-response relationship exists between the amount of prilocaine administered and the incidence of methemoglobinemia. Breakdown products from the metabolism of the local anesthetic are likely responsible (Hjelm and Holmdahl 1965). In the case of prilocaine, oxidation of hemoglobin to methemoglobin is caused by *o*-toluidine, a product of prilocaine metabolism.

ALLERGIES. Although allergic-type reactions to the amide local anesthetics are rare, it is possible for the aminoester local anesthetics such as procaine to cause hypersensitivity or anaphylactic responses. Most commonly implicated is PABA, a product of ester metabolism. Other potential causes of allergic reactions are preservatives contained in local anesthetic solutions. Methylparaben is one such agent that is reported to be chemically similar to PABA.

ADDICTION. Since the use of cocaine in clinical veterinary practice is virtually nil, the issue of human abuse potential is not commonly discussed in texts focused on veterinary medicine. However, abuses of this drug both directly (i.e., by humans with access to the compound) and indirectly (e.g., administration to horses as a stimulant prior to a race) are still possibilities worthy of this brief mention and of further thought and consideration by the reader.

CLINICAL PHARMACOLOGY. Clinically important properties of local anesthetics include anesthetic potency, speed of onset of action, duration of anesthetic action (Table 15.1), and differential sensitivity to anesthetic action. These properties are influenced by a number of other factors, such as dose of drug, site of injection, addition of vasoconstrictor to the injectate, and carbonation and pH adjustment of the local anesthetic (Strichartz and Berde 1994).

Anesthetic Potency. Lipid solubility, or hydrophobicity, seems to be a primary determinant of intrinsic anesthetic potency. The smaller and more lipophilic the molecule, the faster the rate of interaction with the sodium channel receptor. However, the relationship is less clear clinically than in the studies of isolated nerve preparations. The relative potencies of agents as determined in in vivo preparations are highly dependent not only on intrinsic factors but also on anatomic and physiologic factors (Strichartz et al. 1990). Water solubility (hydrophilicity) is also important for diffusion to the site of local anesthetic action.

Onset of Anesthetic Action. In isolated nerves the onset of local anesthetic action is related to the agent's physicochemical properties. In the patient, onset of action is also influenced by agent dose or concentration. A larger number of molecules of anesthetic in the region of the nerve facilitates more rapid action (and prolongation of effect).

DOSE OF ANESTHETIC AGENT. Use of a greater volume of anesthetic or a more concentrated solution increases the number of agent molecules in the region of the nerve. This facilitates a more rapid anesthetic onset and increases the probability and duration of successful anesthesia. When injected in the epidural or intrathecal space, increased volume of local anesthetic solution will also influence the spread of the agent.

CARBONATION AND PH ADJUSTMENT. In the isolated nerve preparation, addition of bicarbonate to the local anesthetic solution results in a more rapid onset of nerve blockade at a reduced anesthetic concentration (Wong et al. 1993). Controversy exists concerning the merits of this practice under clinical conditions. The reasoning behind this practice is that by increasing the pH of the solution, the amount of drug in the uncharged base form is increased, which should increase the rate of anesthetic diffusion and modify the dose required and time of onset of action.

USE OF HYALURONIDASE. Addition of this mucolytic enzyme is thought to enhance the diffusion of local anesthetic agents to the site of action (e.g., peripheral nerve). However, it may also enhance systemic absorption (and so toxicity) and is currently not felt to be cost-effective.

Duration of Anesthetic Action. The duration of anesthetic action of local anesthetics varies (Table 15.1). In vivo duration of action is influenced not only by the anesthetic's intrinsic action on nerves but also by its action on local blood vessels. All agents except cocaine tend to have a biphasic effect on vascular smooth muscle. At low concentrations local anesthetics tend to cause vasoconstriction, whereas in clinical doses vasodilation is usually present. Consequently, the duration of block may be shorter in vivo than that determined in isolated nerve preparations.

SITE OF INJECTION. Duration of action is inversely related to the absorption of the drug from the injection site. This is generally independent of the agent used. Hence the shortest duration of action is usually seen following intrathecal administration and the longest duration following the peripheral nerve blocks (e.g., brachial plexus, sciatic).

USE OF A VASOCONSTRICTOR. Addition of a vasoconstrictor to the local anesthetic solution decreases local perfusion, delays the rate of vascular absorption of local anesthetic, and therefore prolongs anesthetic action. Epinephrine (5 µg/mL, or 1:200,000) is the agent most commonly added to the local anesthetic. Others, such as phenylephrine and norepinephrine, are also used but without substantial clinical advantage over epinephrine. A potential reason for the occasional failure of clinical benefit from the addition of epinephrine is related to the low pH of the epinephrine preparation; when added to the local anesthetic, the low pH has the potential to further reduce the free base available for diffusion through tissues, thus delaying the onset of the local anesthetic block.

INFLUENCE OF VARYING BARICITY. Although perhaps of less consequence in veterinary patients due to their horizontal posture (four-legged stance), varying the baricity of local anesthetic solutions will influence the spread of these agents within the spinal cord. Hypobaric solutions (i.e., with a specific gravity less than that of cerebrospinal fluid [CSF]) will tend to migrate to nondependent areas, whereas hyperbaric solutions (i.e., those with a specific gravity greater than that of CSF) will migrate from the site of injection to dependent areas. This is a frequently applied technique with human patients but rarely or at least infrequently considered in veterinary patients.

MIXTURES OF LOCAL ANESTHETICS. The basis of mixing local anesthetics is to enhance onset and prolong the duration of neural blockade. While this may indeed work in some clinical situations, it is not universally effective. This is likely due to drug interactions that negate these potentially beneficial effects. For example, in isolated nerve studies, it has been suggested that when chloroprocaine (short onset and duration) and bupivacaine (long onset and duration) are mixed, metabolites of chloroprocaine may inhibit the binding of bupivacaine to receptor sites. At present there appears to be little clinically significant benefit to the use of mixtures of local anesthetics.

Pregnancy. Plasma cholinesterase activity is reduced with pregnancy and, this will influence the duration of the ester local anesthetics. The spread and depth of epidural or spinal local anesthetic is also reported to be greater in pregnant patients. Mechanical factors (such as engorged epidural vasculature) causing a decrease in the size of the spinal and epidural space have been implicated, as have hormonal changes (higher progesterone levels) associated with pregnancy. It is therefore advisable to reduce the dose of local anesthetics administered via this route in these patients.

USES OF LOCAL ANESTHETICS. Local anesthetics are most often used to produce regional anesthesia (Table 15.5). Some may also occasionally be used to provide analgesia, supplement actions of IV and inhalation anesthetics, and prevent or treat cardiac dysrhythmias. Rarely, an agent such as lidocaine may be administered in low dose to suppress grand mal seizures and to prevent or treat increases in intracranial pressure.

Regional anesthesia is a term loosely used to refer to a variety of applications of local anesthetics for anesthetic purposes. The term implies that a region of the body is affected as opposed to the entire body as with general anesthesia. The region affected may be very limited or broad in scope. In terms of organization, regional anesthesia includes the subcategories listed below.

Topical Anesthesia. Surface, or topical, anesthesia results when the drug is applied to the skin or mucous membrane to cause loss of sensation by paralyzing sensory nerve endings. Local anesthetics are widely used on the mucous membranes of the eye, nose, and mouth. Most are ineffectively used on unbroken skin, because cornified epidermis limits penetration. The recent introduction of a combination of lidocaine and prilocaine in a eutectic mixture has overcome this problem and is now commonly used to provide dermal analgesia for venipuncture and catheterization (Gajraj et al. 1994).

Local Infiltration. Infiltration anesthesia is perhaps the most common method of regional anesthesia and consists of making numerous subcutaneous (SC) injections of small volumes of local anesthetic solution into the tissues. The drug diffuses into surrounding tissue from the site of injection and anesthetizes nerve fibers and endings. Large amounts of relatively dilute solutions are often infiltrated into operative sites.

Peripheral Nerve Block. Peripheral nerve block (conduction block) is produced by injection of local anesthetic in the immediate vicinity of individual peripheral nerves or a nerve plexus. Paravertebral nerve blocks in

cattle (Horney 1966) and horses (Moon and Suter 1993), intercostal nerve blocks, and the brachial plexus block are peripheral nerve blocks. Intrapleural anesthesia is an alternative to multiple intercostal nerve blocks and may be considered a regional peripheral nerve block.

Intra-articular Administration. Local anesthetics may be administered via the intra-articular route to facilitate diagnosis of lameness, as is commonly done in the horse. The technique may also be used to desensitize the affected joint prior to and following surgical intervention (e.g., arthroscopy).

Intravenous Block. Intravenous local or regional anesthesia is accomplished by IV injection of large volumes of dilute local anesthetic into an extremity isolated from the rest of the circulation by a tourniquet. The apparent mechanism of action is by diffusion of local anesthetic across blood vessels to local nerves. Normal nervous and muscle function returns quickly upon release of the tourniquet, which allows blood flow to dilute the regional local anesthetic concentration. The technique is frequently used for operations of the digit in cattle (Weaver 1972; Bogan and Weaver 1978; Skarda 1987).

Epidural Block. Injecting local anesthetic solution into the epidural space generally at the lumbosacral space (dog, pig) or first or second intercoccygeal space (horse, cow; sometimes referred to as caudal anesthesia) produces epidural or extradural anesthesia. The anesthetic acts upon the posterior spinal nerves before they leave the vertebral column. The extent of anesthetic action is dependent on the spread of the drug and diffusion to neural tissues from the site of injection.

Spinal (Subarachnoid) Block. Spinal block is produced by injecting local anesthetic into the subarachnoid space, generally (in veterinary patients, e.g., sheep, cat) at the lumbosacral space. Because the vertebral level of termination of the spinal cord varies among animal species, this form of anesthesia is technically more difficult than epidural injection. Readers are referred to Skarda 1987 and veterinary anesthesia textbooks such as Thurmon et al. 1996 for further information on these techniques in animals.

LOCAL ANESTHETIC AGENTS

Aminoester Local Anesthetics

COCAINE HYDROCHLORIDE. Although it was the first local anesthetic to be used clinically, cocaine is no longer used in veterinary practice due to its highly addictive nature. It is classified as a Schedule II drug, and its use is highly regulated. Despite minimal or no clinical use in veterinary medicine, information about cocaine is of interest historically because of its continued common use in human patients, its abuse by humans, and its potential for illicit use in performance animals.

Cocaine Hydrochloride, USP (Fig. 15.2), is a white crystalline substance readily soluble in water. The alkaloidal form is sparingly soluble in water but freely soluble in organic solvents. Alkaloidal cocaine is not used orally or parenterally. Local anesthetics chemically related to cocaine are esters of PABA, with the alkyl amine introduced into the alkyl group.

ADMINISTRATION. The primary route of administration is via direct application to mucous membranes, through which it penetrates rapidly. Because it penetrates the horny epidermis slowly, cocaine is not sufficiently effective when applied to the intact skin. Cocaine will anesthetize tissues into which it is infiltrated, but it is no longer employed in this manner because of its high tissue toxicity. Although it has been suggested that cocaine is destroyed or hydrolyzed by gastric secretions following ingestion, evidence indicates that cocaine is not inactivated and can be rapidly absorbed from the gastrointestinal tract (Van Dyke et al. 1978).

ACTION. Sensory nerve endings are completely and reversibly paralyzed upon local contact with cocaine. For a number of years this drug was looked upon as the most effective of the local anesthetics for production of surface anesthesia. However, local anesthetics with comparable potency and no addicting potential are now more commonly employed clinically.

Local vasoconstriction characteristically occurs following application of cocaine to tissue. Cocaine blocks uptake of catecholamines at adrenergic nerve endings and is the only common local anesthetic possessing this action. Consequently, it sensitizes the sympathetic effector mechanism so that effector cells give an exaggerated response to catecholamines. In addition to vasoconstrictor action, the pupil of the eye is dilated following topical use of cocaine. Ophthalmologists have found it useful for inducing mydriasis in eye examinations as well as for concurrent local anesthesia of the eye.

DURATION. Duration of local anesthesia from cocaine depends on concentration and site of application of the solution. Concentrations as low as 0.02% applied locally to susceptible tissues will produce fleeting anesthesia. Higher concentrations may produce local anesthesia lasting as long as 0.5 hour.

THERAPEUTIC USE. Cocaine should be used only for topical anesthesia. Cocaine solutions in concentrations of 5-10% are used to anesthetize mucous membranes of the nose, larynx, and buccal cavity in large animals. In smaller species, concentrations of 5% are adequate.

TOXICITY. Acute toxicity from cocaine can occur clinically due to a drug overdose, rapid absorption, or improper administration. Adverse or toxic effects from

SC use in the horse can occur at a dose as low as 600 mg. However, excitation has been reported when only 180 mg cocaine was injected hypodermically. Severe toxic effects without fatality occur in the horse following IV administration of cocaine at doses of 0.93-1.13 mg/kg. A dose as low as 120-180 mg (presumably injected by the IV route) can be lethal in the horse. On a body weight basis (i.e., mg/kg), the horse is more sensitive to cocaine than humans. The computed range of safety that should not be exceeded when cocaine is used on mucous membranes of the horse is 300-420 mg. Cocaine is cumulative upon repeated injection; no tolerance develops from its continued use. The cocaine LD_{100} for a variety of species is given in earlier editions of this text.

The first toxic effect of cocaine is stimulation of the CNS followed by violent convulsive seizures. If sufficient cocaine is given, stimulation is followed by a period of depression that may terminate in unconsciousness and death from respiratory paralysis. Cocaine also induces cardiotoxicity that may be associated with an overstimulation of the adrenergic system. Chronic poisoning or addiction to cocaine may occur in animals under unusual conditions, but addiction is generally limited to humans.

TREATMENT OF COCAINE TOXICITY. An antagonist to the cardiotoxic effect of cocaine has been experimentally achieved by use of *Nitrendipine* (INN) (Baypress), a calcium modulator and chemically a dihydropyridine (Trouve and Nahas 1986). It does not depress the myocardium and has a coronary vasodilator action.

When simultaneously administered intra-arterially with cocaine (2 mg/kg/min) in rats, nitrendipine (1.46 µg/kg/min) suppresses the cardiac arrhythmia produced by cocaine. It also increases the survival time about 4 times, and the dose of cocaine required to produce death is increased more than 4 times. It protects the heart from the acute morphologic lesions induced by cocaine administration and suppresses some of the CNS effects of cocaine (Trouve and Nahas 1986).

Fleming et al. (1990) have reviewed the pharmacology and therapeutic applications with regard to anesthetic management.

PROCAINE HYDROCHLORIDE. *Procaine Hydrochloride,* USP (Novocaine), is a white crystalline powder that dissolves in an equal weight of water. The chemical structure is given in Fig. 15.1. It is relatively stable while exposed to air and also in aqueous solution. A minor degree of deterioration in a solution of procaine is indicated by a yellowish tint. A distinct yellowing or a darkening of the solution indicates that it should be discarded.

Procaine was synthesized after cocaine was discovered to be habit forming and relatively toxic. Procaine is still a commonly used local anesthetic, although it is not very effective as a surface, or topical, anesthetic.

ACTION. The solution of procaine is nonirritant and promptly effective when injected subcutaneously. Anesthesia is relatively brief because the drug is absorbed rapidly and destroyed quickly by plasma cholinesterases. Anesthesia with procaine is commonly prolonged by addition of a vasoconstrictor to the solution to delay absorption from the site of injection.

METABOLISM AND EXCRETION. Procaine is hydrolyzed primarily in blood plasma by nonspecific pseudocholinesterases. Hydrolysis of procaine is rapid. For example, following rapid IV injection of procaine (1000 mg), the plasma concentration of the drug decreases with a half-life of about 25 minutes (Tobin et al. 1976).

Two products of procaine degradation are PABA and diethylaminoethanol. PABA exhibits no local anesthetic action, but diethylaminoethanol has a part of the full anesthetic activity of procaine. PABA inhibits the action of sulfonamide antibiotics and interferes with the chemical determination of sulfonamide concentration in biological fluids. As mentioned previously, allergic reactions to ester local anesthetic agents are attributed to this metabolite.

The kidney excretes procaine and PABA. The pK_a of procaine, a weak organic base, is 8.9 (Table 15.1). The nonionized form of procaine passes more readily through cell membranes than the ionized form. Consequently, an important factor in excretion of procaine is the urinary pH (Evans and Lambert 1974). In the horse, e.g., urinary pH may fluctuate diurnally from the alkaline to the acid side; the pH may also fluctuate depending upon whether the animal is at rest or exercising. A single dose of 60 mg procaine administered intramuscularly in the horse requires an elimination time of 27.5 hours after injection (Evans and Lambert 1974). Acidification of urine with ammonium chloride hastens excretion of ionized procaine; e.g., 600 mg, or 10 times the above dose, administered intramuscularly as a single dose requires only 10 hours for complete elimination.

TOXICITY. The greatest difference between the toxicities of procaine and a potent local anesthetic such as cocaine is rate of metabolism. Cocaine is slowly metabolized, whereas procaine is rapidly detoxified. An LD_{50} of procaine is detoxified in the cat within 20 minutes, whereas an LD_{50} of cocaine is metabolized in 60 minutes. Table 15.6 gives average LD_{50} data for procaine in four species of animals.

CLINICAL USES. Procaine is used in veterinary medicine for infiltration and nerve block (Table 15.5). For infiltration in small animals, a concentration of 1% is generally employed, whereas in larger animals, 2% is preferable. About 2-5 mL of a 2% solution are used for nerve block (conduction) anesthesia in small animals. In large animals, 5-10 mL of a 4% solution are most commonly used. Epinephrine solution may be added to give a concentration of 1:100,000, i.e., 1 mL epinephrine solution (1:1000) to each 99 mL anesthetic solution. Procaine is rarely used for surface

TABLE. 15.6—Average LD_{50} of procaine (g/kg)

	Route	
Species	SC	IV
Guinea pig	0.43	0.05
Rabbit	0.46	0.055
Cat	0.45	0.045
Dog	0.25	—

Source: Graubard and Peterson 1950.

anesthesia because it is not very effective via this route of administration.

The horse seems to be more sensitive to CNS stimulation by procaine than other species of domestic animals. Rapid IV injection of 1000 mg in Thoroughbred mares elicited variable signs of CNS excitation for as long as 4 minutes in a study by Tobin et al. (1976). Considerably larger doses are necessary to produce central stimulation in the cow, whereas the response by the pig is intermediate between that of the horse and cow. Because of its CNS stimulant and analgesic actions, procaine has been used illegally in racing animals to attempt to improve their performance and/or to mask lameness in track and racing events.

Procaine is sometimes combined with other drugs because in doing so a less soluble drug is produced, prolonging drug action. A combination of procaine with penicillin G results in an antibiotic that is absorbed very slowly and prolongs detectable (therapeutic) concentrations in plasma and urine. When using large doses of procaine-penicillin G, the side effects of procaine (see above) should be considered. This also has implications during drug testing for potential abuse in racing and performance animals.

CHLOROPROCAINE HYDROCHLORIDE. *Chloroprocaine Hydrochloride,* USP (Nesacaine) is characterized by a rapid onset and short duration of action. It has a low potency but may be used in higher concentrations (3%) due to its low systemic toxicity. This compound, which has the addition of a chlorine atom to the benzene ring of procaine, is hydrolyzed 3 times more rapidly than procaine. It is hydrolyzed by plasma cholinesterase to 2-chloroaminobenzoic acid and 2-diethylaminoethanol.

Chloroprocaine may be used for infiltration and IV anesthesia, but its main use is via the epidural route for obstetrical anesthesia. Thrombophlebitis following IV administration is reported and likely related to concentration of drug administered. When concentrations of less than 0.5% of preservative-free 2-chloroprocaine are used, this effect is negated. Prolonged neural deficits following its use have been reported, which are now believed to be caused by the preservative sodium bisulfite and not the parent drug itself.

TETRACAINE HYDROCHLORIDE. *Tetracaine Hydrochloride,* USP (Pontocaine), is a potent ester local anesthetic (Fig. 15.2, Table 15.1). It is used to provide topical anesthesia of the eye, nose, and throat and for spinal anesthesia when both sensory and motor blockade are desired. Its rapid absorption from mucosa to which it is applied increases the potential for systemic toxicity in light of its slower metabolism (than that of procaine) by plasma cholinesterase. Both a patch application system and a gel preparation have been evaluated for percutaneous analgesia with favorable results (McCafferty and Woolfson 1993).

BENZOCAINE. *Benzocaine,* USP (Americaine), previously referred to as ethyl aminobenzoate, is structurally similar to procaine except that it lacks a terminal diethyl amino group. It is available as a dusting powder or in oil as an ointment for surface application. It has been used to varying degrees in dentistry to provide anesthesia of the gums and buccal mucosa. Cutaneous application is also reported. Its low solubility allows it to remain localized in wounds to provide long-term analgesia. Benzocaine is also a component (as is tetracaine) in a topical local anesthetic mixture known as cetacaine, which is commonly used as a spray to anesthetize the larynx prior to intubation.

In fish, benzocaine (50 mg/L) induces sedation within 30 seconds after immersion (Oswald 1978). This permits weighing of the fish and injection of the calculated anesthetic doses of other anesthetic drugs.

Benzocaine is relatively nonirritating to tissues, and following absorption it is metabolized to PABA and acetyl PABA. It has been reported to cause methemoglobinemia in some species (e.g., sheep), which may limit its widespread use in clinical practice.

PROPARACAINE HYDROCHLORIDE. *Proparacaine Hydrochloride,* USP (Alcaine, AK-Taine, Ophthetic), is an ester-type local anesthetic about equal in potency to tetracaine. It is chemically distinct from procaine and exhibits little cross-sensitivity. Unlike some topical anesthetics, it produces little or no tissue irritation (Ritchie and Greene 1990). Because proparacaine induces little discomfort upon instillation into the human eye, it is widely used as an ophthalmic anesthetic.

Aminoamide Local Anesthetics

LIDOCAINE HYDROCHLORIDE. *Lidocaine Hydrochloride,* USP (Xylocaine, Lidocaine HCL) (α-diethylaminoaceto-2,6-xylidide), is a white or slightly yellow powder with a characteristic odor (Fig. 15.1). It is relatively stable but nearly insoluble in water. Lidocaine is available as a sterile aqueous solution from 0.5 to 5% with or without epinephrine and in a gel preparation from 2 to 5%.

Lidocaine is one of the most versatile and one of the most (if not the most) widely used of the local anesthetics in veterinary medicine. It is an amide-type local anesthetic and therefore an agent of choice for use with individuals sensitive to the ester-type agents (e.g., procaine).

METABOLISM AND FATE. Lidocaine is relatively quickly absorbed from the gastrointestinal tract and following injection (Boyes et al. 1971; Keenaghan and Boyes 1972). The rate of systemic absorption following parenteral administration is slowed and the duration of action is prolonged when lidocaine is used with a vasoconstrictor.

Lidocaine is metabolized in the liver by mixed-function oxidases at a rate nearly as rapid as that for procaine. The unchanged form is excreted in urine of the dog in a concentration of 10-20%. Two metabolites have been identified in the dog from hepatic *N*-deethylation of lidocaine (Wilcke et al. 1983). One of these, monoethylglycinexylidide, has significant pharmacologic activity; after a second *N*-dealkylation, glycinexylidide (4-hydroxy-2,6-dimethylaniline) is formed. Both compounds may be further hydroxylated to 4-hydroxy-2,6-xylidine, which is the major metabolite excreted in the urine.

Following administration of lidocaine (10 mg/kg) in pregnant guinea pigs, it rapidly crosses the placenta (Finster et al. 1972). High concentrations are found in the fetal liver, heart, and brain. The liver of the fetal guinea pig is the only organ in which lidocaine is found in higher concentration than in the maternal subject.

The kinetics and oral absorption rate of lidocaine have been determined in the dog (Boyes et al. 1970); 78% of the administered dose reaches the general circulation. Emesis occurs regularly at 2.5 hours after administration.

The pharmacokinetics of lidocaine in humans is given in Table 15.2. Pharmacokinetic data have also been reported for the dog after the IV and IM administration of single doses (6 mg/kg) of lidocaine hydrochloride (Wilcke et al. 1983). The mean elimination rate constant and mean specific clearance for IV lidocaine in the dog are 0.786/hr and 2.4 L/kg/hr, respectively. After IM administration, the mean absorption rate constant is 7.74/hr. Absorption is essentially complete (91.9%) after an IM injection of lidocaine (Wilcke et al. 1983).

In the dog, administration of an IV loading dose of 0.8 mg/kg/min over 10 minutes, followed by an infusion of 0.085 mg/kg/min over 3 hours, provides a steady-state plasma concentration of 3.5-5.5 µg/mL (DeRick et al. 1981). In a simulation of an IM dose schedule for lidocaine (6 mg/kg every 1.5 hours) in the dog, an average serum concentration of 1.48 µg/mL is expected, which is near the therapeutic range (Wilcke et al. 1983).

CLINICAL USES. Lidocaine is used for all forms of local anesthesia (Table 15.5). In addition to its use as a local anesthetic, it is used intravenously as an antiarrhythmic agent and also as a supplement to general anesthesia (Phillips et al. 1960). It decreases the requirement for inhalation and injectable anesthetics (DiFazio et al. 1976; Himes et al. 1977, 1979; Kissin and McGee 1982; Doherty and Frazier 1998).

PRILOCAINE HYDROCHLORIDE. *Prilocaine Hydrochloride*, USP (Citanest), is a local anesthetic of the amide type (Fig. 15.2) whose pharmacological properties resemble those of lidocaine (Table 15.1). However, it causes significantly less vasodilation and hence may be used without the addition of epinephrine to prolong the duration of effect. It is also reported to be the least toxic of the amide local anesthetics and so best suited for IV anesthesia. Methemoglobinemia is a side effect of overdose and accounts for its declining use, especially for human patients.

EUTECTIC MIXTURE OF LIDOCAINE AND PRILOCAINE (EMLA). A eutectic mixture of local anesthetics (EMLA) consisting of a 1:1 mixture of lidocaine and prilocaine is available commercially for transcutaneous application. It has been shown that when the base forms of these two compounds are mixed, an oil is formed at temperatures over 18° C (Brodin et al. 1984). This eutectic mixture is commercially available in a preparation containing arlacton as an emulsifier and carbapol as a thickening agent. Each gram (mL) contains 25 mg of lidocaine and 25 mg of prilocaine. The reported bioavailability is 3% for lidocaine and 5% for prilocaine (Klein et al. 1994). This may, however, vary with the site of application and skin pigmentation and condition.

EMLA has been evaluated as a percutaneous analgesic prior to venipuncture in dogs, cats, rabbits, and rats (Flecknell et al. 1990). Its efficacy following a 60-minute application was good in dogs, cats, and rabbits but questionable in study rats. In human adults, the efficacy is improved following a 90-120 minute application. Hence, in people the general recommendation is to apply the emulsion to the cutaneous tissue using an occlusive dressing for a minimum of 60-90 minutes prior to application of a noxious stimulus (Bjerring and Arendt-Nielsen 1990; Buckley and Benfield 1993). Analgesic benefits have been shown for at least 30 minutes following removal of the emulsion in human patients.

The toxicity of EMLA is related primarily to the metabolism of prilocaine to *o*-toluidine, which can result in methemoglobinemia, as mentioned previously. It is not recommended for use in human neonates due to the immature methemoglobin reductase enzyme. In 6- to 12-month-old human infants, a maximum dose of 2 grams is suggested (Engberg et al. 1987; Buckley and Benfield 1993). Blanching or hyperemia may be noticed in the area of application following removal of the occlusive bandage and is likely due to the relative vasoactivity of the two compounds.

MEPIVACAINE HYDROCHLORIDE. *Mepivacaine Hydrochloride*, USP (Carbocaine), is a local anesthetic of the amide type (Fig. 15.2). Its pharmacological properties are similar to those of lidocaine. Although actual potency figures vary, it is about equal (or slightly less) in local anesthetic potency to lidocaine (Table 15.1). It has a slightly longer duration of action, likely due to less intrinsic vasodilator activity than lidocaine. While its use in clinical practice is similar to that of lidocaine

(Table 15.5), mepivacaine is not recommended for obstetrical anesthesia, because its actions are markedly prolonged in the fetus. In the adult, the toxicity of mepivacaine is about 1.5-2 times that of procaine but slightly less than that of lidocaine.

BUPIVACAINE HYDROCHLORIDE. *Bupivacaine Hydrochloride*, USP (Sensorcaine, Marcaine), is an amide-type local anesthetic chemically related to mepivacaine (Fig. 15.2). Bupivacaine is a long-acting local anesthetic. It is about 4 times more potent than lidocaine (Table 15.1) and has a duration of action that ranges from 3 to 8 hours. It is used most commonly for regional and epidural nerve blocks and was the first local anesthetic agent to show significant separation of sensory and motor blockade, making it the drug of choice for obstetrical anesthesia. Central nervous system and cardiac toxicity result from lower doses and blood levels than those reported for lidocaine.

ETIDOCAINE HYDROCHLORIDE. *Etidocaine Hydrochloride*, USP (Duranest), is a long-acting derivative of lidocaine (amide type, Fig. 15.2). It is about equal in potency and toxicity to bupivacaine. Unlike bupivacaine, however, etidocaine shows little separation between sensory and motor blockade and hence, while valuable during surgical anesthesia, is less useful for obstetrics and postoperative pain management.

ROPIVACAINE HYDROCHLORIDE. *Ropivacaine Hydrochloride*, USP (Naropin) (1-propyl-2′6′-pipecoloxylidide hydrochloride monohydrate) is a new long-acting aminoamide local anesthetic that is structurally related to mepivacaine and bupivacaine (Fig. 15.2). Ropivacaine differs from mepivacaine and bupivacaine in that it is an *S*-isomer, whereas the latter agents are racemic mixtures (previous studies of isomers of local anesthetics suggested that the systemic toxicity of the *S*-isomer of various compounds may be less than that of racemic preparations). The physicochemical properties of ropivacaine are similar to those of bupivacaine with the exception of its lipid solubility (ropivacaine is substantially less lipid soluble) (Rosenberg and Heinonen 1983; Rosenberg et al. 1986). Its pharmacokinetic profile following IV administration is given in Table 15.2 (Arthur et al. 1988). At low concentrations ropivacaine has intrinsic vasoconstricting properties, whereas higher concentrations result in vasodilation.

Ropivacaine is used in a manner similar to bupivacaine (Table 15.5). Reports indicate that the motor block following epidural administration is less dense and of a shorter duration than for bupivacaine. This, along with ropivacaine's reduced cardiotoxic potential when compared to bupivacaine (Feldman et al. 1989; Reiz et al. 1989), offers advantages for clinical use when differential blockade is desired. Ropivacaine also reportedly caused fewer CNS symptoms in human volunteers and was at least 25% less toxic than bupivacaine with regard to the dose tolerated (Scott et al. 1989). See McClure 1996 for a recent review.

ANTICONVULSANTS

Pathophysiology of Seizures. The normal resting membrane potential (RMP) of the neuronal cell is –70 mV. The electrical difference across the cell membrane is maintained by a Na^+,K^+-ATPase (adenosine triphosphatase) pump. Depolarization and the generation of an action potential occur when the RMP becomes sufficiently positive to reach threshold. As in other cells, the RMP of a neuron is determined by the concentration of negative and positive ions across the membrane. The concentration reflects ion flux and thus permeability of the cell membrane to the ions. Fluxes resulting in an increase in positive ions inside the cell relative to the outside hypopolarize the RMP, bringing it closer to threshold and subsequent depolarization. The tendency of a neuron to depolarize reflects, in part, the sum total effect of neurotransmitters (NTs) interacting with the cell membrane. Inhibitory NTs such as γ-aminobutyric acid (GABA) render the RMP more negative and less susceptible to depolarization. Excitatory NTs such as acetylcholine and glutamate elevate the RMP to a more positive status and thus make it more susceptible to reaching the threshold necessary for depolarization. Inappropriate depolarization may reflect a number of abnormalities, such as alteration of the Na^+,K^+ pump, permeability changes in the cell membrane (induced, e.g., by hypoxia, inflammation, or trauma), altered concentrations of excitatory (increased) or inhibitory (decreased) neurons, or altered cellular metabolism.

Seizures are the clinical results of rapid, excessive neuronal discharge in the brain. Seizures are classified as primary (i.e., genetic) or secondary (acquired) and as generalized or focal. Generalized seizures are much more common in small animals; the incidence is greater in dogs than in cats. With seizure onset of a generalized character, convulsive electroencephalographic activity begins simultaneously in all brain regions (Faingold 1985). Many seizures in epileptic subjects have been attributed to a cortical origin. However, there is increasing evidence that the brain stem can exhibit self-sustained seizure discharge, and this area of the brain may serve an important role in the generation and expression of generalized tonic convulsions (Browning 1985). Within the brain stem, the pontine reticular formation is believed to play a key role in the generation and/or expression of tonic convulsions. Studies indicate that the ability to depress reticular core activity is an essential characteristic of antiepileptic drugs, which suggests that the reticular formation is involved in the spread and generalization of clinical seizures (Fromm 1985).

In the dog, the most common form of epilepsy is generalized tonic-clonic, or grand mal, seizures (Cunningham 1984; Schwartz-Porsche et al. 1985). Epilepsy and other seizure disorders of the central nervous system (CNS) in the dog may be caused by an acquired organic lesion such as brain tumor, head trauma, toxicosis, electrolyte imbalance, hypoglycemia, renal failure, or hepatic disease (acquired, or secondary, epilepsy); or may be genetic or inherited ("true," idiopathic, or primary epilepsy). An autosomal gene associated with a sex-linked suppressor on the X chromosome may explain the higher incidence of seizures in male dogs.

Status epilepticus refers to failure of the patient to recover to a normal alert state between repeated tonic-clonic attacks or episodes that last at least 30 minutes (Delgado-Escueta et al. 1982). Convulsive, or tonic-clonic, status epilepticus is a medical emergency in which convulsive seizures must be terminated by treatment with anticonvulsant agents. In humans, epileptic seizures must not be allowed to persist more than 60 minutes if severe and permanent neurologic injury or death is to be avoided (Delgado-Escueta et al. 1982). The longer an epileptic seizure persists, the greater the incidence of mortality and morbidity. Hyperthermia due to continuous muscle contraction may become life threatening during continued seizure activity.

Biochemical Aspects of Epilepsy. Until the underlying biochemical mechanisms leading to genesis of epileptic seizures are better understood, all therapy administered for control of seizures will continue to be directed toward treatment of symptoms. Although experimentally induced CNS seizures have provided valuable information regarding some of the biochemical events preceding and following a seizure, the question always remains whether the induced seizure simulates those observed in the clinical setting.

In humans, amino acid analysis of plasma in subjects with epilepsy indicates much higher concentrations of taurine (2-aminoethanesulfonic acid) and glutamic acid than in normal subjects (van Gelder et al. 1975). Also, the glutamic acid in urine is elevated in subjects that are known epileptics. Oral administration of taurine does not appreciably affect concentrations of amino acids with the exception of glutamic acid. In human patients with an abnormal plasma concentration of glutamic acid, administration of taurine lowers the glutamic acid in the normal direction along with a drop in urinary excretion (van Gelder et al. 1975). Consequently, taurine administration appears to partially reverse these biochemical abnormalities. According to van Gelder and associates, there is little doubt that, in both the CNS and the periphery, taurine serves a major physiologic and biochemical function by regulating glutamic acid levels in the tissue. Moreover, the central role of glutamic acid in the metabolism of the cell (energy, protein synthesis, pH regulation, Ca^{++} retention) may explain why correcting its concentration with taurine has a beneficial effect on experimentally induced epilepsy.

Taurine is important in the maintenance of osmotic equilibrium across cell membranes (Thurston et al. 1981). In chronically hypernatremic animals, brain amino acids are significantly increased. The greatest increases in the brain are in GABA, glycine, glutamate, and taurine. Physiologically, GABA and glycine have well-known NT inhibitory roles in reduction of CNS excitability. Extensive research is needed to determine if other biochemical factors besides taurine are involved in modulation and/or reversal of the epileptiform seizure. The efficacy and safety of employing taurine in treatment and control of seizures remain to be established.

General Mechanisms of Anticonvulsant Action. Seizures can be initiated by four general mechanisms conducive to pharmacologic manipulation: (1) altered neuronal membrane function, which can lead to excessive depolarization; (2) decreased inhibitory NTs, such as GABA, the most potent inhibitory NT in the CNS; (3) increased excitatory NTs, such as glutamate; and (4) altered extracellular potassium and calcium concentration. An increase in extracellular potassium and a decrease in calcium, which occur during a seizure, increase neuronal excitability and facilitate the initiation and spread of the seizure. Once initiated, the seizure discharge may synchronize with other neurons and propagate to surrounding areas in the brain. Anticonvulsants block seizure initiation and propagation by blocking abnormal events in a single neuron or the synchronization of related neurons. Drugs acting at more than one point (e.g., phenobarbital) tend to be most effective. Drugs active at the GABA receptor also tend to be particularly efficacious. The GABA receptor interacts with several other drugs as well as with GABA. Response to anticonvulsant drugs may vary with the origin of the seizure. For example, using kindling-induced seizures in cats, Sumi (1993) demonstrated differences in response of temporal lobe epilepsy to phenobarbital, depending upon whether the seizure originated from the hippocampus or amygdaloid tissues.

General Pharmacokinetic Considerations of Anticonvulsant Drugs. Epilepsy is controlled, not cured; control of canine epilepsy is possible only in 60-70% of the cases (Parker 1982). Generally, treatment must be administered for the life of the animal (Frey 1986). The most common anticonvulsant drugs used in veterinary medicine are phenobarbital, primidone, diazepam, and potassium bromide. The disposition of each of the anticonvulsant drugs may impact the efficacy of the drug.

Absorption determines time to peak effect as well as magnitude of effect. Most anticonvulsants are given either orally or intravenously (IV). General statements regarding absorption are limited to the oral route. Most of the anticonvulsants are well absorbed following oral administration. An exception is phenytoin, which is so variable that bioavailability can be as little as 40%, varying dramatically among products. Phenobarbital is characterized by almost 100% bioavailability, although food will slow the rate of absorption of phenobarbital and probably other anticonvulsants. Peak plasma drug concentrations of anticonvulsants may occur as late as 4-6 hours after administration. Thus, when monitoring drug concentrations, peak samples should not be collected until 4-5 hours after administration. Fasting prior to sample collection is preferred.

Most anticonvulsant drugs are lipid soluble and are distributed to a volume that exceeds total body water (i.e., greater than 0.6 L/kg). Distribution into the CNS is important for all anticonvulsant drugs; at steady state, all anticonvulsant drugs sufficiently distribute into the CNS. The rate of CNS distribution following IV administration is of concern in a patient with status epilepticus. The drug must be sufficiently lipid soluble to be rapidly distributed into the CNS in therapeutic concentration. Diazepam is the most lipid soluble anticonvulsant and very rapidly distributes in the CNS. Phenobarbital is less lipid soluble, and therapeutic effects may take as long as 15 minutes to be achieved. Binding to serum proteins limits the amount of free drug and thus the rate and amount of drug distribution into the CNS. Diazepam is greater than 90% protein bound; however, its lipid solubility is so great that distribution into the CNS is sufficiently rapid in patients in status epilepticus. Phenytoin is also highly protein bound but is less lipid soluble; thus, it does not distribute rapidly into the CNS. Phenobarbital is less than 50% protein bound.

Because they are lipid soluble, most anticonvulsants must be eliminated by hepatic metabolism. Metabolism of anticonvulsant drugs can have a profound effect on therapeutic success. The effect in part depends upon the effects of phase I metabolism on the particular drug (i.e., inactivation, activation, or generation of toxic compounds). In general, most anticonvulsants are slowly metabolized. An exception is diazepam, which has a short half-life. In contrast to its action in humans, phenytoin is very rapidly metabolized in dogs (half-life less than 2 hr).

A consequence of phase I metabolism may be activation to a compound of equal, greater, or less anticonvulsant efficacy compared to the parent drug. Primidone must be metabolized in the liver to its active metabolite, phenobarbital, before it is effective in dogs. Clorazepate, a benzodiazepine, is also a prodrug, but it is converted in the stomach to its active metabolite. Although diazepam is rapidly metabolized, its duration of pharmacologic effect is prolonged since most of its metabolites have some degree of anticonvulsant effect. The half-lives of the metabolites may also be longer than that of the parent compound.

Safety of anticonvulsant drugs is profoundly affected by metabolism. Phase I metabolites, by their nature, are reactive. Although intended to progress to phase II metabolism, some reactive metabolites can interact with and damage surrounding tissues. Hepatotoxicity is a common side effect of long-term anticonvulsant use. The greater the amount of drug metabolized, the greater the potential toxicity.

The relationship between half-life and dosing interval is important to successful anticonvulsant therapy (see Table 16.1). Half-life will determine dosing interval and time to steady state. The relationship between dosing interval and half-life determines the rate of drug accumulation (or lack thereof). If the drug half-life is substantially smaller than dosing interval, plasma drug concentrations markedly fluctuate during the dosing interval, which may be undesirable. Toxic concentrations may occur postdosing, followed by subtherapeutic concentrations at the end of the dosing interval. If the patient misses a dose, seizures may occur. Because therapeutic concentrations are achieved with each dose, giving an extra dose to a seizuring patient may help control seizures during an episode. Shortening the interval may also help by decreasing fluctuations between peak and trough. When monitoring, both peak and trough samples should be collected in order to characterize the degree of fluctuation in plasma drug concentrations.

If the drug half-life of an anticonvulsant is substantially longer than the dosing interval, fluctuation in plasma drug concentrations is minimized. Since much of the previous dose(es) is still in the body at the administration of each new dose, plasma drug concen-

TABLE 16.1—Relationship between drug half-life and dosing interval in anticonvulsant therapy

Drug	Dose (mg/kg)[a]	Route	Dosing interval	$t_{1/2}$	Time to steady state[b]	Therapeutic range[b]
Clorazepate	0.5–1.0	PO	8 hr	<12 hr	<24 hr	150–400 ng/mL[c]
Diazepam	1–2	PO	8 hr	<3 hr	<24 hr	As above
	0.5–2.0[d]	IV	5–10 min			
	5–20[e]	IV inf	60 min			
Felbamate	15	PO	Divided 8–12 hr	<8 hr	<24 hr	—
Phenobarbital	2	PO	12 hr	56–102 hr	2–3 wk[g]	20–45 µg/mL
	3–6[f]	IM				
	3–16[f] total	IV inf	60 min			
	6–12[h]	IV slow				
Primidone	10[i]	PO	12 hr	56–102	hr 2–3 wk[g]	As above
Bromide	30	PO	12–24 hr	24 d	2–3 mo	1–3 mg/mL[j]

[a] Maintenance dose unless otherwise noted is starting dose; doses are dependent on patient response and serum drug concentrations.

[b] Extrapolated from human literature unless noted otherwise.

[c] Based on an ongoing clinical trial.

[d] Can be repeated up to 3 times for control of life-threatening seizures.

[e] Diluted in either 5% dextrose or 0.9% NaCl; first flush 50 mL through polyvinyl catheter to allow for binding of diazepam.

[f] Following diazepam for management of life-threatening seizures.

[g] Half-life is likely to shorten with chronic therapy.

[h] Loading dose as sole drug for management of life-threatening seizures.

[i] Based on phenobarbital as the active anticonvulsant.

[j] Lower concentrations may be effective when combined with phenobarbital.

trations accumulate until a steady state is reached. At this point, the amount eliminated during each dosing interval is equal to the amount dosed with each interval. Each daily dose represents only a small amount of drug in the animal. In this situation, giving an extra dose to the seizuring patient will do little to increase plasma drug concentrations and thus to stop seizures. Missing a dose will probably not result in seizures since little drug will be eliminated during that time period. Shortening the dosing interval in this scenario is also not likely to help. In contrast to drugs with a short half-life, only a single sample needs to be collected for monitoring of drugs with a long drug half-life since peak and trough samples are not likely to be substantially different during a single dosing interval.

Any drug metabolized by the liver can potentially induce drug-metabolizing enzymes, and drug interactions are a common sequela. The type of interaction is difficult to predict and varies with each drug combination. Phenobarbital is the most potent inducer of drug-metabolizing enzymes known. The rate of drug metabolism will increase clearance, and (assuming patient volume of distribution does not change) elimination half-life of many drugs will decrease. Phenobarbital increases its own rate of metabolism. Phenytoin is also a potent enzyme inducer. It can decrease the drug concentration of phenobarbital. However, it can also compete with phenobarbital for metabolism, resulting in an increase in the concentration of one or the other drug. These effects are not predictable. Clorazepate increases concentrations of phenobarbital (reason unknown).

Phenobarbital Sodium. *Phenobarbital Sodium,* USP (soluble phenobarbitone, Luminal sodium), was the second barbituric acid derivative of clinical importance to be developed. It was synthesized in 1912 in Germany and patented under the trade name of Luminal. Phenobarbital is only slightly soluble in water, so a readily soluble sodium salt was prepared.

MECHANISM OF ACTION. Phenobarbital sodium specifically depresses the motor centers of the cerebral cortex, giving it excellent anticonvulsant properties. Electroshock experiments in cats and other species have established phenobarbital as one of the most potent anticonvulsants available. It has the widest spectrum of activity in different convulsive seizure patterns. Most other antiepileptic agents have been synthesized as structural variants of phenobarbital (de Angelis 1979). For example, primidone is a close congener of phenobarbital.

Phenobarbital is the most effective anticonvulsant to inhibit the progressive intensification of seizure activity that may accompany epilepsy. Phenobarbital both increases the seizure threshold required for seizure discharge and decreases the spread of discharge to surrounding neurons. The primary means by which phenobarbital decreases seizure activity is by enhancing responsiveness to the inhibitory postsynaptic effects of GABA. Interaction of GABA with phenobarbital opens a chloride channel, resulting in higher intracellular concentrations of chloride and hyperpolarization of the RMP. However, phenobarbital also inhibits glutamate activity and probably calcium fluxes across the neuronal membrane. Phenobarbital can be considered a "broad-spectrum" anticonvulsant. Despite introduction of new antiepileptics, phenobarbital remains the anticonvulsant of choice in the cat and dog (Schwartz-Porsche et al. 1985). It is effective in all types of epileptic seizures observed in cats and dogs (Kay and Fenner 1977).

DISPOSITION. As a weak acid (pK_a 7.3), phenobarbital is absorbed well following oral administration, although peak plasma concentrations may not be reached for 4-6 hours after administration. The absorption half-life in dogs is 1.27 ± 0.21 hours (Pedersoli et al. 1987). About 6.4 hours is required for near complete absorption of phenobarbital from the gastrointestinal (GI) tract. Absorption is 88-95% complete. Phenobarbital is 45% bound to serum proteins in dogs (Frey and Löscher 1985). Its volume of distribution in dogs is 0.7 ± 0.15 L/kg. To attain steady-state serum concentrations, 8-15.5 days of multiple dosing is necessary. Maintenance doses of 1.8 mg/kg 3 times a day or 5.5 mg/kg once daily administered orally are required to reach an average serum concentration of 20 μg/mL (Ravis et al. 1984).

Through microsomal enzyme action, phenobarbital is metabolized by oxidative hydroxylation to form hydroxyphenobarbital. This metabolite has weak anticonvulsant activity and does not contribute significantly to the action of phenobarbital. In the dog, hydroxyphenobarbital is rapidly eliminated from blood by conjugation with glucuronide and excretion in urine. Up to 25% of the parent drug is eliminated renally in dogs. Alkalinization of urine accelerates excretion of unaltered phenobarbital because the process of back-diffusion (tubular reabsorption) is reduced appreciably by ionization of the drug (de Angelis 1979). Individual variability in the rate of phenobarbital elimination is marked due to differences in hepatic metabolism. Half-life varies not only between and within species but also in the same animal. Phenobarbital is a potent inducer of hepatic drug-metabolizing enzymes and is capable of increasing the rate of clearance of other drugs metabolized by the liver as well as increasing its own rate of metabolism (see Drug Interactions).

In the dog, phenobarbital (2 mg/kg) administered orally 3 times a day for 5 days results in an elimination half-life between 37 and 75 hours, with a mean elimination half-life of 53 ± 15 hours (Ravis et al. 1984). In dogs following a single 5 mg/kg IV dose, clearance is 5.6-6.6 mL/kg/hr, and elimination half-life is 92.6 ± 23.7 hours (Pedersoli et al. 1987). The effects of multiple doses of phenobarbital were documented by Ravis and coworkers. Following 90 days of treatment (5.5 mg/kg), mean elimination half-life decreased from 88.7 ± 19.6 to 47.5 ± 10.7 hours (Ravis et al. 1989).

Phenobarbital volume of distribution is 0.96 ± 0.060 L/kg in horses (Knox et al. 1992; Ravis et al. 1987; Duran et al. 1987). Following a single IV dose of 12 mg/kg (infused over 20 min), phenobarbital reached an extrapolated peak serum concentration of µg/mL and was characterized by a distribution half-life of 6 minutes. The elimination half-life of phenobarbital is short: 18 hours. The apparent volume of distribution at steady state was 0.8 L/kg, similar to that of other species, but total body clearance was rapid, at 0.03 L/hr/kg (Duran et al. 1987). Following single oral administration of 5.5 mg/kg, peak concentrations of µg/mL were achieved at 11 hours and the elimination half-life was 19 ± 4 hours and mean residence time was 37 hours (Ravis et al. 1987). Oral bioavailability was 101%, with a mean absorption time of 11 hours. A daily dose of 11 mg/kg administered once daily was recommended by the authors based on this dose. As in other species, multiple administration of phenobarbital results in changes in drug disposition. Mean elimination half-life of phenobarbital decreases from 24.2 ± 4.7 to 11.2 ± 2.3 hours, and clearance increases from 28.2 ± 5.1 to 57.3 ± 9.6 mL/hr/kg (Knox et al. 1992). In foals, IV phenobarbital (20 mg/kg) undergoes first-order elimination (Spehar et al. 1984); its elimination half-life is 12.8 ± 2.1 hours. Although foals are sedated by phenobarbital for the first 1-2 hours, they can walk but are ataxic. Additionally, some hyperexcitability occurs 3-8 hours after the phenobarbital infusion (Spehar et al. 1984).

Side Effects

BEHAVIOR. Polyphagia, polydipsia, and polyuria are side effects that occur in animals receiving clinical dosages of phenobarbital (Kay and Fenner 1977). The polyuric effect is apparently due to an inhibitory action in release of antidiuretic hormone. Identical sedative side effects are observed in the dog after treatment with phenobarbital or primidone (Schwartz-Porsche et al. 1985). Dogs appear fatigued and listless after receiving either drug; some are weak in the rear legs, and ataxia occurs. All of these effects may be long lasting and may persist in some cases for the duration of treatment.

HEPATOTOXICITY. At high plasma drug concentration doses (i.e., greater than 30-40 µg/mL), phenobarbital appears to be hepatotoxic. Animals whose livers are induced and thus require high doses of phenobarbital to maintain drug concentrations in the lower therapeutic range may also be more susceptible to toxicity because of increased formation of metabolites. Phenobarbital will also cause nonpathologic changes in hepatic clinical laboratory tests due to induction of enzymes. Serum alkaline phosphatase (SAP) and the transaminases are likely to increase with prolonged therapy (Chauvet et al. 1995). These are not necessarily indicative of liver disease. Changes associated with true hepatic pathology are more likely with primidone (see below). Moderate elevations in serum alanine transferase and SAP, coupled with changes in bile acids and bilirubin, are more indicative of hepatic pathology (i.e., liver disease). Serum albumin and cholesterol also may decrease (Chauvet et al. 1995). Hepatic function tests (e.g., serum bile acids) should be used to monitor the development and/or progression of liver disease. The incidence of serious liver toxicity can be reduced by avoiding combination therapy, using therapeutic monitoring to achieve adequate serum concentrations at the smallest dose possible, and evaluating clinical pathology changes every 4-6 months while the patient is on therapy. Note that, due to the effects of hypoxia, etc., liver enzymes are generally increased following a seizure.

NEUROENDOCRINE EFFECTS. Phenobarbital given orally and daily for 2 weeks to infant rats at 60 mg/kg and 15 mg/kg produces a 12 and 3%, respectively, reduction in brain growth (Diaz and Schain 1978). Although it is known that brief exposure of newborn animals to various drugs may result in behavior and brain alterations later in life, information is lacking on the short- or long-term effects of phenobarbital. In addition to alteration in the brain weight, phenobarbital fed to rats as 0.25% of their diet results in a reduced gain in body weight (Peraino et al. 1980). It is suggested that the lower weight gain in animals chronically exposed to phenobarbital occurs from alterations in hepatic metabolism; however, the effect of phenobarbital upon food intake may also be a factor in growth reduction.

In one study of 5 dogs receiving phenobarbital for 12 months, endogenous ACTH concentrations increased, although they remained within reference limits. Plasma ACTH-stimulated aldosterone concentration also increased over the course of the study (Chauvet et al. 1995).

REPRODUCTION. Administration of phenobarbital to pregnant rats from day 12 to day 19 of gestation suppresses weight gain and induces significant effects on reproductive function of their offspring (Gupta et al. 1980). Some of these effects are delay in onset of puberty, disorders in the estrous cycle, and infertility (Gupta and Yaffee 1982). Additionally, animals exposed to phenobarbital in utero have altered concentrations of sex steroids, gonadotropic hormones, and estrogen receptors. These studies suggest that phenobarbital exposure during prenatal growth can induce permanent changes in sexual development (Gupta et al. 1980). Pregnant animals treated with phenobarbital are more sensitive or responsive to its depressant effects than nonpregnant animals (Middaugh et al. 1983). Consequently, phenobarbital should be used cautiously during pregnancy and at a minimum therapeutic dose.

DRUG INTERACTIONS. Hepatic microsomal enzyme activity, especially mixed-function oxidase induction, is accelerated by phenobarbital. Enzyme induction by phenobarbital appears to be dose related (Tavernor et al. 1983). Long-acting barbiturates are better inducers of microsomal enzyme activity than are short-acting compounds. Compared on a molar basis, phenobarbital is the most potent enzyme stimulatory agent known (Valerino et al. 1974). Pentobarbital and thiopental sodium are less potent inducers of microsomal enzyme activity. Enzyme induction may take weeks to months and may occur with each dose increase. Induction has been documented in dogs (Aldridge and Neims 1979; Bekersky et al. 1977; Ciaccio and Halpert 1989; McKillop 1985). Once enzyme induction is initiated by exposure to phenobarbital, it may take up to 7 months for its complete disappearance in the dog after treatment has stopped. Phenobarbital does appear to induce its own elimination, although drug-metabolizing enzymes responsible for phenobarbital metabolism may not be as impacted as enzymes responsible for metabolism of other drugs (e.g., antipyrine) (Abramson 1988a). Antipyrine metabolism in dogs treated with phenobarbital increased up to 13-fold, potentially converting a "capacity-limited" drug to a "flow-limited" drug (Abramson 1988b).

In newborn rats, phenobarbital induces a long-term, perhaps permanent, alteration in hepatic mixed-function oxidase activity (Faris and Campbell 1981).

If rats are treated with phenobarbital, the weight of their livers is increased. An increase occurs in the amount of microsomal protein per gram of liver as well as in the content of cytochrome P-450. The result of the increased level of enzyme is a more rapid rate of drug metabolism in treated animals. In fetal rat livers, phenobarbital significantly increases the metabolic destruction of hexobarbital by 263% over controlled conditions (Sunouchi et al. 1984). Induction of drug-metabolizing enzymes is likely to necessitate a larger dose in order to maintain the same drug concentration.

Treatment with phenobarbital stimulates hepatic drug-metabolizing enzymes in several other animals, including swine, sheep, and cattle (Conney and Burns 1972). Administration of low doses of phenobarbital to lactating cows given DDT for several days results in a significant decline in the content of DDT metabolites in milk (Alary et al. 1971).

Phenobarbital is likely to increase the metabolism and clearance of other drugs cleared by the liver. The clinical sequelae depend on the role of hepatic metabolism in the disposition of the drug. The most clinically important sequelae are the generation of toxic metabolites and therapeutic failure due to decreased drug efficacy. Increased metabolism may also increase formation of an active drug from a prodrug; and it may promote tumors (Kitagawa et al. 1979).

In the dog, prolonged administration of phenobarbital (180 mg/day orally) decreases the bioavailability of propranolol, a β-adrenergic blocking agent, from 8 to 35% (Vu et al. 1983). Additionally, it alters the binding, metabolism, and pharmacokinetics of propranolol (Bai and Abramson 1983). Phenobarbital shortens the duration of β blockade by propranolol. The clearance of thiopental is increased in Greyhounds treated with phenobarbital for 14 days (Sams and Muir 1988). Duration of anesthetic effects of xylazine is decreased in dogs pretreated with phenobarbital for 4 days (Nossaman et al. 1990). Although phenobarbital had no effect on clorazepate concentrations in one study (Forrester et al. 1993), in our laboratory clorazepate concentrations decreased in patients receiving phenobarbital. Phenobarbital is likely to increase adverse response to toxins whose toxicity reflects reactive metabolites. A seven-to ninefold increase occurs in the toxicity of carbon tetrachloride after treatment of sheep with phenobarbital and DDT (Seawright et al. 1972). Phenobarbital pretreatment potentiates the toxic response of renal cortical slices of the rabbit to chloroform in vitro (Bailie et al. 1984). Cephaloridine nephrotoxicity in rabbits is potentiated by phenobarbital (Kuo et al. 1982).

Treatment of animals with phenobarbital increases activity of microsomal enzymes that metabolize endogenous hormones. Estrogens, androgens, progestational steroid, and adrenocortical steroid hydroxylation are increased. Thyroid hormones (e.g., thyroxine) are decreased due to increased hepatic metabolism and possibly increased deiodination. Animals may test as hypothyroid despite lack of clinical signs. Accelerated hydroxylation of steroidal hormones by microsomal enzymes is influenced in vivo by an increased metabolism and altered physiologic action of the steroids. Because it stimulates increased hepatic microsomal enzyme activity, phenobarbital may be a tumor-promoting agent (Kitagawa et al. 1979). In the presence of 2-methyl-*N*, *N*-dimethyl-4-amino-azobenzene, a noncarcinogen in rats, hepatocellular carcinomas develop by 72 weeks when animals have been treated simultaneously with phenobarbital.

An interaction involving phenobarbital, phenytoin, and vitamin D may lead to development of rickets or osteomalacia. An interaction between phenobarbital and griseofulvin may decrease griseofulvin blood levels by impairing absorption of the antifungal agent (de Angelis 1979).

Enzymes responsible for phenobarbital metabolism are subject to effects of drugs that inhibit drug-metabolizing enzymes. Ciaccio et al. (1987) demonstrated the inhibitory effects of chloramphenicol on phenobarbital metabolism.

TREATMENT OF PHENOBARBITAL TOXICOSIS. Artificial respiration with oxygen should be administered to prevent hypoxia from respiratory arrest induced by overdoses of phenobarbital. Although less effective than oxygen, doxapram or other analeptic drugs may be used to stimulate the respiratory center. Also, alkalinization of the urine accelerates renal excretion of phenobarbital via increased ionization of phenobarbital by this alkalinization (de Angelis 1979). Activated charcoal effectively accelerates the body clearance of phenobarbital (Berg et al. 1982). When charcoal is administered in the human, the biologic half-life of phenobarbital is decreased from 110 ± 8 to 45 ± 6 hours; it increases the total body clearance of phenobarbital from 4.4 ± 0.2 to 12.0 ± 1.6 mL/kg/hr (Berg et al. 1982).

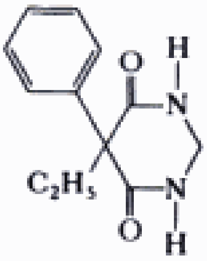
PREPARATIONS. Phenobarbital is available as oral or injectable preparations. Oral tablets contain 1/4-, 1/2-, or 1-grain (15, 30, and 65 mg, respectively) phenobarbital. An elixir is also available (4 mg/mL) for treatment in very small animals. The injectable form is intended for IV use but can be given intramuscularly (IM). Under the 1970 Controlled Substances Act, phenobarbital is classified as a Schedule IV drug.

CLINICAL USE. Phenobarbital has a more specific depressant effect upon convulsive seizures than any other barbiturate. It can be an effective anticonvulsant at clinical dosages that produce minimal sedation (Macdonald and Barker 1978). Phenobarbital has long been used in the symptomatic or prophylactic control of convulsive seizures of epilepsy. It is effective in 60-80% of canine patients suffering from epilepsy if serum concentrations of the drug are maintained within recommended therapeutic ranges of 15-40 μg/mL. Patients are not considered refractory to phenobarbital therapy until concentrations reach 35 μg/mL. Due to a large individual variability in phenobarbital clearance, required dosages for dogs can be as little as 1 mg/kg to greater than 15 mg/kg every 12 hours to control seizures, although hepatotoxicity may be more likely at high doses and concentrations (Schwartz-Porsche et al. 1985). Therapeutic monitoring can be used to ascertain the dosage regimen necessary to achieve and maintain therapeutic serum concentrations in the individual patient. Marked variability in the elimination of this drug occurs between dogs and in the same animal depending on duration of therapy. In patients with a drug half-life of 36 hours or less, the same total dose at 8-hour intervals may be useful since plasma drug concentrations may drop below therapeutic ranges during a 12-hour dosing interval in some animals.

A loading dose of 12 mg/kg can be administered to avoid delay in therapeutic effects in the dog. With this dose range, the plasma concentrations of phenobarbital fall within the range of 20-40 μg/mL that has been proposed in treatment of human epilepsy. In animals where complete control of the seizure is not possible, Schwartz-Porsche and associates (1985) administered daily oral doses of phenobarbital up to 17 mg/kg.

In the cat, an oral dose (4 mg/kg) every 12 hours is suggested; the total daily IV dose in the cat was 15-60 mg in one study (Kay and Fenner 1977). More recently, following a single IV administration of 10 mg/kg, phenobarbital reached an extrapolated peak serum concentration of μg/mL that ranged from 8.8 to 12.7 in cats and was characterized by an apparent volume of distribution of 0.93 L/kg and an elimination half-life of 58 ± 4 hours. A single oral 10 mg/kg dose yielded a similar half-life, a peak serum concentration that ranged from 11.0 to 16.6 μg/mL, and a bioavailability of 120% (Cochrane 1990a). Following multiple oral administration of 5 mg/kg, peak concentrations were 5.7 to 7.2 μg/mL at the first dose and 18 to 22 μg/mL at 21 days, and elimination half-life was 43 ± 3 hours. Induction apparently occurs with chronic administration in cats, following administration of the same dose for 21 days (Cochran 1990b). For terminating status epilepticus in the cat, 60-120 mg phenobarbital has been recommended IM or to effect by the IV route. Phenobarbital at 10 mg/kg IV was effective in controlling experimentally induced (pentylenetrazol) interical spikes in 7 of 10 cats. At this dose, phenobarbital also slightly depressed the heart rate and blood pressure (by 10 mm Hg) of treated cats. Phenobarbitial was also useful for controlling seizures induced experimentally following injection of tetanus toxin in the hippocampus of cats (Darcey and Williamson 1992) and in kindling seizures induced in the hippocampus or amygdalus (Sumi 1993). Concentrations of 15-25 μg/mL were effective for generalized seizures of hippocampal origin, although concentrations up to 50 μg/mL were necessary to control afterseizures (Sumi 1993). Amygdaloid-induced seizures, in contrast, were much more resistant to phenobarbital. In equine neonatal seizure disorders, an IV loading dose of phenobarbital (20 mg/kg) diluted in 30-35 mL sterile saline and infused over 25-30 minutes is recommended; maintenance doses of 9 mg/kg at 8-hour intervals should also be infused slowly (Spehar et al. 1984). A phenobarbital serum concentration of 15-40 μg/mL should be achieved. In epileptic chickens, phenobarbital plasma concentrations between 12.6 and 17.1 μg/mL provide complete protection against intermittent photic stimulation-induced seizures for 6 hours (Johnson et al. 1977). Based upon required plasma concentrations, seizure processes in humans and epileptic fowl show comparable sensitivity to antiepileptic action of phenobarbital. Compared to use of phenytoin (Davis et al. 1978), phenobarbital provides complete protection from seizures in the chicken without signs of toxicity. When based on dosage requirements, the benzodiazepines (clonazepam, diazepam) are the most potent anticonvulsants in epileptic fowl (Johnson et al. 1979).

Primidone. *Primidone,* USP (Mylepsin, Mysoline) (*5*-phenyl-*5*-ethylhexahydropyrimidine-4,6-dione) (Fig. 16.1), is a close congener of phenobarbital. The drug is a white, crystalline, tasteless substance. Primidone is approved by the FDA for use in the dog for control of convulsions associated with "true" (primary) epilepsy, epileptiform seizures, virus encephalitis, distemper, and "hardpad" disease. It may be the most commonly used antiepileptic agent in veterinary medicine (Cunningham 1984). According to Schwartz-Porsche et al. (1982), only primidone and phenobarbital are effective in treatment of epilepsy in the dog. Although primidone therapy does not appear to have an advantage over phenobarbital therapy in control of seizure disorders, this does not exclude the possibility that a single animal may respond more favorably to one or the other (Farnbach 1984; Schwartz-Porsche et al. 1985). Primidone is less well tolerated than phenobarbital because of its potential for inducing hepatotoxicity (Schwartz-Porsche et al. 1985).



Primidone

FIG. 16.1

Pharmacologic Activity. In humans, approximately 60-90% of an oral dose of primidone is rapidly absorbed from the GI tract, with a peak serum level being attained in about 3 hours (de Angelis 1979). In animals, primidone is oxidized at carbon-2 (C-2) to phenobarbital and ring cleavage at C-2 to phenylethylmalondiamide (PEMA). Although all three compounds have anticonvulsant activity, most of primidone's anticonvulsant activity in dogs results from phenobarbital: as the compound with the longest half-life, it accumulates to the highest concentrations (Cunningham et al. 1983). The potency of primidone and PEMA is 1/30 of that of phenobarbital. The efficacy of primidone generally is equal to or less than that of phenobarbital, and anticonvulsant activity can be correlated to serum phenobarbital levels. Because of this relationship, serum phenobarbital concentrations can and should be used to guide design of primidone dosing regimens (Cunningham et al. 1983). Target therapeutic ranges are the same as for phenobarbital. Primidone continues to be used in patients which have proven refractory to phenobarbital at the maximum therapeutic drug concentration (i.e., 40 µg/mL). Note that its efficacy in this scenario has not been proven. Efficacy may simply reflect improved conversion to phenobarbital (i.e., animals that are induced may metabolize the drug to greater concentrations of phenobarbital than those generated from administration of phenobarbital alone). According to Farnbach (1984), there is no advantage in using primidone rather than phenobarbital for control of epilepsy in most dogs.

Although primidone is less potent than phenobarbital as a general CNS depressant, it is considered to be more potent in protection of animals against maximal seizures induced by electroshock and pentylenetetrazol. Primidone is more toxic in cats and rabbits than in rats or mice; it is not recommended for therapeutic use in cats. Cats metabolize primidone to phenobarbital to a lesser extent than dogs. This may be why it is far less effective in cats than in dogs (Frey 1986).

Disposition. Primidone is well absorbed following oral administration. IV administration can be associated with undesirable side effects; in addition, as a prodrug, it is not preferred for emergency therapy. In dogs, 3.8 mg primidone is converted to 1 mg phenobarbital. In cats, the conversion of primidone to phenobarbital is less effective (Sawchuk et al. 1985). Peak plasma concentrations of primidone are much higher in cats than in dogs and peak plasma concentrations of phenobarbital are much lower (<50%) when the same dosing regimens are used in both species. Thus, while the drug may appear to be safe in cats, the recommended dose may not be sufficient to be effective.

Side Effects. Identical sedative side effects are seen in the dog after treatment with phenobarbital and after treatment with primidone (Schwartz-Porsche et al. 1985); see the discussion on antiepileptic action of phenobarbital. Primidone will cause all of the side effects noted for phenobarbital. Primidone may induce nystagmus, nausea, drowsiness, and ataxia. According to Schwartz-Porsche et al. (1985), polydipsia is more common in dogs treated with primidone. In humans, it is recommended that therapeutic plasma concentrations of primidone and its metabolite phenobarbital not exceed 15 µg/mL and 30 µg/mL, respectively. Megaloblastic anemia is one of the more serious adverse effects of primidone in humans.

In the dog, primidone induces progressive hepatic injury as manifested by increases in liver enzyme values (Meyer and Noonan 1981). In a clinical study, signs of liver toxicity were reported in 14 of 20 dogs (Schwartz-Porsche et al. 1985). Hepatic cirrhosis associated with primidone and phenobarbital after 7 years of use has been reported in a dog (Poffenbarger and Hardy 1985). Dermatitis is a rarely reported side effect (Henricks 1987).

In humans, long-term (more than 2 years) treatment of epileptic patients with primidone has been associated with development of osteomalacia; subnormal serum calcium is seen in such patients. Primidone may induce or stimulate increased production of hepatic microsomal enzymes that increase the metabolism or degradation of vitamin D.

Primidone should not be used concurrently with chloramphenicol, which is a potent inhibitor of the microsomal enzyme system. Severe CNS depression and inappetence occur in the dog after concurrent use of these drugs (Campbell 1983).

Clinical Use. In the early 1950s, primidone was used in veterinary medicine for control of convulsive seizures in the dog soon after it was introduced into human medicine for clinical use (Chastain and Graham 1978). Primidone should be reserved for treatment of seizures in the dog that have not responded to phenobarbital administered at doses sufficient to achieve 30-40 µg/mL. Only 1/15 of dogs refractory to phenobarbital can be expected to respond to primidone. The recommended dose for primidone is 30-55 mg/kg/day (or 5-15 mg/kg every 8 hours). Because of gradual or progressive microsomal enzyme induction, complete control of seizures in the dog can sometimes be attained only with daily oral doses of 50 mg/kg;

however, daily oral doses as high as 107 mg/kg may fail to control seizure disorders in the dog (Schwartz-Porsche et al. 1982, 1985). When primidone is substituted for another antiepileptic agent, the dosage should be gradually increased while gradually withdrawing the dosage of the drug being replaced over a period of at least 15 days so that adequate seizure control is maintained (de Angelis 1979). If converting from phenobarbital to primidone, a conversion ratio of 250 mg primidone per 65 mg phenobarbital can be used. Therapeutic monitoring should be used to guide therapy. Toxicosis to primidone, manifested as temporary ataxia and signs of depression, has been reported in cats after administration of single doses ranging from 10 to 25 mg/kg. The safety of doses necessary to achieve therapeutic concentrations of phenobarbital has not been documented in the cat.

Primidone has been used in the Thoroughbred foal to control recurrent convulsive seizures (May and Greenwood 1977). Daily doses consisted of 1-1.5 g administered by stomach tube.

Phenytoin Sodium. *Phenytoin Sodium,* USP (Dilantin sodium, Epanutin), previously named diphenylhydantoin, depresses motor areas of the cortex (antiepileptic action) without depressing sensory areas. It is approved by the US Food and Drug Administration (FDA) for use in the dog for control of epileptiform convulsions.

Phenytoin is a hydantoin derivative (de Angelis 1979); others, of lesser importance, are mephenytoin and ethotoin. Hydantoins are five-membered ring structures, whereas barbiturates are six-membered structures. A major point of difference between the hydantoins and barbiturates is the absence of a C=O group. Phenytoin is not a general anticonvulsant, as is phenobarbital, and is not used for emergency treatment of poisoning by convulsant drugs or tetanic seizures.

Oral preparations are available in suspension, capsule, and tablet forms. Phenytoin (50 mg/mL) is also available for human use in a special solvent for IV administration. IV injection of the drug causes a marked drop in arterial pressure and is not advised in the dog (Pasten 1977). Absorption of phenytoin is erratic following IM administration. This may be related to crystallization of the drug at the injection site because of alteration in pH by tissues (de Angelis 1979). Administration of phenytoin by the IM route is not advised, because considerable necrosis and sloughing at the injection site occur (Pasten 1977). Absorption of the drug from the GI tract of the dog is poor (Sanders and Yeary 1978). Bioavailability of phenytoin from the tablet formulation averages 36% in the dog (Frey and Löscher 1980). In the horse, a bioavailability of 34.5 ± 8.6% has been reported (Kowalczyk and Beech 1983).

Phenytoin has declined in use for control of seizures in the dog because of lack of efficacy (Sanders and Yeary 1978), which may be related to decreased bioavailability and rapid clearance. Phenytoin is much less effective in the dog than either phenobarbital or primidone in control of epileptic seizures (Farnbach 1984). The half-life of phenytoin is too short in the dog to permit maintenance of adequate drug concentrations in plasma and the CNS (Schwartz-Porsche et al. 1985). When administered alone, phenytoin cannot be considered a satisfactory drug for treatment of epilepsy in the dog (Frey and Löscher 1980; Frey 1986). Due to drug interactions and enhanced hepatotoxicity, a combination of phenytoin with phenobarbital is not a viable alternative.

In the cat, phenytoin is relatively toxic and generally undesirable as an anticonvulsant (Kay and Fenner 1977). Studies are needed to determine the efficacy and safety of phenytoin in cats (Frey 1986).

PHARMACOLOGIC ACTIVITY. Phenytoin produces a stabilizing effect upon synaptic junctions that ordinarily allow nerve impulses to be readily transmitted at lower thresholds. Consequently, the level of synaptic excitability that permits impulses to be transmitted easily is reduced and/or stabilized. This effect appears to be associated with active extrusion of Na^+ from neurons and decrease of posttetanic potentiation or spread of nerve impulses to adjacent neurons. There is also a possibility that phenytoin reduces movement of calcium across cell membranes. Phenytoin may inhibit activation of protein phosphorylation by the calcium-calmodulin complex (Marx 1980). Phosphorylation and norepinephrine release in neurons require calmodulin.

Reduction in spread of the "burst" activity associated with epilepsy prevents genesis of the cortical seizure. The activity of phenytoin in stabilizing hyperexcitable neurons so that epileptic seizure does not develop occurs without causing general depression of the CNS (de Angelis 1979).

DISPOSITION. Poor oral absorption and differences in product bioavailability (as little as 40% bioavailable) contribute to the difficulty in achieving effective serum levels of phenytoin. The generic preparations of phenytoin should not be used.

At therapeutic concentrations (10-20 μg/mL), phenytoin is highly bound (75-85%) to plasma proteins of animals and humans (Baggot and Davis 1973). The high degree of phenytoin binding predisposes this acidic drug to interaction with other drugs by a displacing effect at protein (albumin) binding sites. In uremic patients, there is a decrease in plasma protein binding of phenytoin. This accelerates renal clearance or elimination of the drug. Phenytoin readily crosses the placenta (Mirkin 1975). High concentrations are attained in the maternal liver and maternal and fetal hearts. The brain (ostensibly the primary target organ) contains nearly the lowest concentration of the drug.

Phenytoin is metabolized into meta- or parahydroxyphenytoin. These metabolites are then conjugated with glucuronic acid. In humans, about 60-75% of the daily dose of phenytoin is excreted in the glucuronide form (de Angelis 1979); the dog also converts a high percentage of phenytoin into this form. In addition, diphenylhydantoic acid, a minor metabolite in some laboratory animals, and dihydrodiol are formed. Interestingly, after treatment with phenytoin high concentrations of diphenylhydantoic acid are found in cat urine. The dihydrodiol metabolite is probably involved in formation of catechol metabolites; these are also formed in most animals (Glazko 1973). Epoxide metabolites are also speculated to be formed in humans. The combined used of phenytoin and phenobarbital or primidone may lead to increased formation of epoxide metabolites in animals. This could possibly result in cholestatic hepatic injury similar to that reported in 3 dogs (Bunch et al. 1987). If epoxide intermediates are formed, mercapturic acid should also be present; however, no such metabolites have yet been identified. Since phenytoin is not very soluble in water, little of the unmetabolized drug is excreted in urine.

Phenytoin has a long duration of action in the cat. The long plasma half-life (ca. 24-108 hours) (Tobin et al. 1973) and the prolonged effect of phenytoin observed in the cat over some of the other species may also be related to the cat's decreased ability to conjugate compounds with glucuronic acid. Phenytoin is excreted after formation of a hydroxylated derivative and conjugation with glucuronic acid or sulfate. A plasma half-life of 108 hours, following oral administration of phenytoin (10 mg/kg) in the cat, has been reported (Roye et al. 1973).

In the dog, despite relatively large single daily doses (50 mg/kg) administered orally, the plasma concentration of the drug is low. Paralleling this observation, the plasma half-life of a single 50 mg/kg dose in the dog is only 6-7.8 hours (Dayton et al. 1967). Roye et al. (1973) found the plasma half-life was 4-6 hours after an IM injection of phenytoin (50 mg/kg). The apparent discrepancy between results of these two studies may be due to pretreatment of the dogs for 9 days with phenytoin by Roye et al. (1973). Studies have shown that the half-life of phenytoin in the dog dramatically decreases after 7-9 days of treatment (Frey and Löscher 1980). Apparently, phenytoin is a potent inducer of the hepatic microsomal enzyme system in the dog (see "Drug Interactions"). Other biologic half-life data reported in the dog are the following: after a single IV dose (15 mg/kg), a value of 4.5 hours was obtained by Sanders et al. (1979b), and a half-life of 3.65 hours was determined by Pedersoli et al. (1981) after an IV bolus of 11 mg/kg.

CLINICAL USE. Recommended therapeutic doses of phenytoin administered orally every 8 hours for control of seizure disorders in the dog show considerable variation: 6.6-11 mg/kg (Pasten 1977), 11 mg/kg (Cunningham 1984), and 35 mg/kg (Sanders and Yeary 1978). In humans, clinical therapeutic effects and intoxication are related to the blood concentration of phenytoin. A reduction in the number of seizures occurs when phenytoin blood concentrations exceed 10 μg/mL.

Since the half-life of phenytoin in the dog is reduced considerably after use for 7-9 days (Frey and Löscher 1980), high oral doses up to 30 mg/kg every 8 hours may be required for satisfactory control of seizures (Cunningham 1984). Oral administration of 4.4 and 11 mg/kg phenytoin every 8 hours fails to achieve the assumed therapeutic level of the drug in serum at 10 μg/mL. The serum content of phenytoin in the dog after single or repeated oral doses of 10 mg/kg does not exceed a concentration of 2 μg/mL (Sanders and Yeary 1978). To achieve a serum concentration of approximately 10 μg/mL phenytoin, it appears that an oral dose of at least 35 mg/kg given 3 times daily is necessary for the adult dog (Sanders and Yeary 1978). Use of phenytoin for control of seizures has declined due to its lack of efficacy, which may be the result of inadequate dosage (Sanders and Yeary 1978). According to Pedersoli et al. (1981), an oral dosage schedule of 20 mg/kg every 8 hours of the phenytoin microcrystalline suspension should be sufficient to reach a serum concentration of 10 μg/mL or higher. However, this dose will only maintain a plasma therapeutic level for the first 2 or 3 days of treatment (Frey and Löscher 1980). The marked variation in the dosage of phenytoin needed to maintain a therapeutic level in the dog is attributable in large measure to its rapid biotransformation by the hepatic microsomal enzyme system.

In the horse, phenytoin administered orally at 8-hour intervals provides average serum steady-state concentrations of 5 and 10 μg/mL with doses of 2.83-8.22 and 5.67-16.43 mg/kg, respectively (Kowalcyzk and Beech 1983). After IV administration of 8.8 mg/kg phenytoin in the horse, the mean biologic half-life is 8 hours.

DRUG INTERACTIONS. Phenytoin must be considered a potent inducer of the hepatic microsomal enzyme system in the dog (Frey and Löscher 1980). Seven to 9 days after administration of phenytoin, its half-life may be reduced from 5.5 to 1.3 hours. In contrast, the half-life after oral administration in humans averages 22 hours, with a range of 7-42 hours. Phenytoin has moderate ability in the human to induce cytochrome P-450 mixed-function oxidase activity (microsomal enzyme induction). Consequently, it is a much more efficacious drug for control of epileptic seizures in humans than in dogs.

Phenytoin and phenobarbital have been used in combination for treatment of epilepsy in both humans and dogs. This combined use is considered optimal therapy for epilepsy in humans (Morselli et al. 1971). Use of both drugs is controversial in animals because both drugs induce hepatic microsomal enzyme activity. The metabolism (i.e., hydroxylation) of phenytoin is increased. Phenytoin likewise increases the metabolism of phenobarbital. This seesaw effect in metabolism of both drugs complicates successful therapy, and the combined use of the drugs is discouraged (Pasten 1977).

Inhibition of phenytoin metabolism by other drugs has been observed in humans. Prolongation of the effect has been reported following simultaneous administration of dicoumarol, chloramphenicol, phenylbutazone, and the phenothiazines. Also, in vitro inhibition of phenytoin metabolism has been seen in the presence of diazepam and propoxyphene hydrochloride. The significance of this in vivo has not been determined. In the dog, an interaction has been seen following clinical use of phenytoin and chloramphenicol (Sanders et al. 1979a). The serum half-life of IV phenytoin is increased from 3 to 15 hours. Increase in the serum half-life is best explained by reduction in rate of metabolism of phenytoin by hepatic microsomal enzymes. Interestingly, the signs of phenytoin toxicosis are reversed within 24 hours after cessation of chloramphenicol treatment (Sanders et al. 1979a). Phenylbutazone is also known to elevate plasma concentration of phenytoin through inhibition of metabolism of phenytoin (de Angelis 1979).

Metabolism of a number of chemicals or drugs is enhanced by phenytoin. These include digitoxin, dexamethasone, DDT, dieldrin, and cortisol (Conney and Burns 1972).

An interaction also exists between phenytoin and vitamin B_6. Serum phenytoin concentration drops after folic-acid therapy probably because the hydroxylase enzyme metabolizing phenytoin is folate dependent. In humans, the usual therapeutic concentration of phenytoin in plasma reduces the half-life of theophylline (a drug used in treatment of airway obstruction) and increases its body clearance about twofold (Marquis et al. 1982). A similar action of phenytoin upon the half-life of theophylline in animals would be expected.

Phenytoin may prolong the prothrombin time (Keith et al. 1983). Blood coagulation defects similar to that induced by vitamin K deficiency can occur in neonates exposed to phenytoin in utero. The coagulation defect can be reversed by treatment with vitamin K.

BLOOD CONCENTRATIONS AND ASSOCIATED TOXICITY. In humans, mild signs of intoxication such as nystagmus develop with blood levels of 20 μg/mL; patients with levels over 40 μg/mL have marked stagmus and are incoordinated and lethargic. Blood levels in the dog would probably have to increase a comparable 100-400% over therapeutic levels as in humans before serious signs of intoxication develop.

Hepatitis, jaundice, and death following clinical use of phenytoin have been reported for one animal (Nash et al. 1977). However, this animal had initially received primidone (500 mg daily) orally for the control of seizures. Toxic hepatopathy and intrahepatic cholestasis associated with phenytoin administration in combination with phenobarbital and/or primidone have been reported in 3 dogs (Meyer and Noonan 1981; Bunch et al. 1987). Induction of enzymes may increase the formation of toxic metabolites and contribute to hepatotoxicity. Hepatotoxicity due to phenytoin is more likely if phenytoin is used in combination therapy with either primidone or phenobarbital. Toxicity may be related to generation of toxic metabolites. Two forms of toxicity appear to occur with phenytoin therapy: a dose-independent chronic hepatitis which may progress to cirrhosis and which appears to be reversible following discontinuation of the drug early in the disease, and a dose-dependent intrahepatic cholestasis, which is accompanied by a poor prognosis.

SIDE EFFECTS. The side effects of phenytoin in a dog are moderate because it is rapidly metabolized (Cunningham 1984). Transient incoordination and oversedation may occasionally occur following administration of phenytoin. A moderate degree of polyphagia, polydipsia, and polyuria may be seen in animals medicated with this drug. Sialosis, weight loss, and vomiting have been reported following the use of phenytoin in the cat. In the horse, head twitching occurs 2-5 minutes after the end of an IV infusion of 8.8 mg/kg (Kowalczyk and Beech 1983). Inhibition of release of antidiuretic hormone accounts for the polyuria that develops after administration of phenytoin. There is also an inhibition of insulin secretion (de Angelis 1979).

In laboratory mice, a single dose of phenytoin administered to pregnant animals on the 9th-14th day of gestation produces various fetal anomalies (Harbison and Becker 1969; Millicovsky and Johnston 1981), including changes in fetal growth. Embryo lethal effects were also reported. However, the intraperitoneal (IP) dose required to produce this teratogenic effect in mice is exceedingly large (7-150 mg/kg). It has been postulated that teratogenesis occurs in mice as a result of formation of a phenytoin-epoxide complex and its covalent binding to gestational tissue. Studies indicate that the development of cleft palate by phenytoin has a common pathway with that produced by glucocorticoids (Katasumata et al. 1982). Both phenytoin and glucocorticoids inhibit ribonucleic acid and protein synthesis in mouse fetal palates. It has been hypothesized that phenytoin and glucocorticoids bind to a common cell receptor. Teratogenesis in the dog from use of phenytoin has not been identified or reported in the veterinary literature.

Rickets, hypocalcemia, decreased duodenal calcium transport, and reduction of calcium-binding protein have been produced in chickens treated with phenytoin (Villareale et al. 1974). These findings suggest that close attention should be given to the calciferol intake in patients requiring epileptic seizure treatment. Calciferol metabolism apparently is altered by phenytoin, which in turn leads to functional vitamin D deficiency. A similar effect in humans has been seen following long-term use of primidone (discussed above).

Benzodiazepines: Diazepam, Clonazepam, and Clorazepate

MECHANISM OF ACTION. Benzodiazepines enhance the inhibitory effects of GABA in both the brain and the spinal cord. Thus they not only decrease seizure spread but also block arousal and centrally depress spinal reflexes. Tolerance to anticonvulsant activity of diazepam develops within 1 week in the dog; thus, diazepam (Valium) is not an effective anticonvulsant for chronic therapy in dogs. However, IV diazepam is the drug of choice for the treatment of status epilepticus in both dogs and cats because it crosses the blood-brain barrier into the cerebral spinal fluid very rapidly. Diazepam (1-2 mg every 8 hr) is also the second-choice anticonvulsant for chronic control of seizures in the cat whose seizures do not respond to phenobarbital; efficacy is equal to phenobarbital. Tolerance to the anticonvulsant effects of clorazepate does not appear to develop in dogs as rapidly as it does to diazepam.

DISPOSITION. Diazepam is the prototype benzodiazepine used in small animals. The drug is well absorbed following oral administration but undergoes rapid and extensive hepatic metabolism once in the circulation. Although only 1-3% of diazepam is orally bioavailable, 74-100% of the drug and all active metabolites are available (Frey and Löscher 1985). Diazepam is generally administered intravenously. It can also be administered intramuscularly, although absorption is not predictable. In human pediatric patients, it has been administered rectally as well. The metabolites of diazepam (nordiazepam and oxazepam) are active, although less so (25-33%) than the parent compound. However, the half-lives of the metabolites are slightly longer than that of diazepam (4 to 6 and 5.2 hr, respectively). In horses, diazepam is characterized by an elimination half-life of 7.5-13 hours (0.05-0.08 mg/kg) and a clearance that ranges between 1.86 and 3.44 mL/min/kg (Shini et al. 1997). Diazepam is still present in plasma at 24 hours. The apparent volume of distribution approximates 2.0-2.25 L/kg. An earlier study (Muir et al. 1982) found elimination half-life to vary between 2.5 and 22 hours, clearance to range between 7 and 9.5 mL/min/kg, and apparent volume of distribution to vary between 1.6 and 3 L/kg. Diazepam is up to 98% protein bound (Klotz et al. 1976). Doses studied ranged from 0.05 to 0.4 mg/kg. Three major metabolites of diazepam detected in horses included n-desmethyldiazpeam, oxazepam, and n-methyloxazepam (Muir et al. 1982).

Following oral administration, metabolite concentration surpasses that of the parent compound. The generation of active metabolites complicates the utility of therapeutic monitoring as a guide to therapy since anticonvulsant activity will not necessarily be correlated with serum diazepam concentrations. All metabolites and parent drugs should be measured. Metabolism in the dog is rapid (half-life of 3.2 hr). Clorazepate is metabolized in the stomach to its active metabolite, nordiazepam (desmethyl diazepam), which is also a major, although less efficacious, metabolite of diazepam.

Diazepam has been studied following rectal administration in dogs (Papich and Alcorn 1995; Mealey and Boothe 1995). Rectal bioavailability of the parent compound approximated only 7.5% at 2 mg/kg and 2.5% at 0.5 mg/kg in one study. However, bioavailability of total metabolites was 79% and 66%, respectively, for each dose in one study and had a mean of 0.517% (range 14-81%) in another, suggesting efficacy following rectal administration (Mealey and Boothe 1995).

PREPARATIONS. Diazepam is available as both an IV and oral preparation; clorazepate is available as an oral preparation. Cautious IV use of the drug must be observed. Use of diazepam in animals has not been approved by the FDA. It is classified as a Schedule IV drug under the 1970 Controlled Substances Act.

SAFETY. Sedation is the most common direct side effect of the benzodiazepines. Adverse effects (sedation, ataxia, increased appetite, and in some cases hyperactivity) are likely to occur if concentrations reach 500 ng/mL. Drug interactions may result in indirect side effects with chronic administration of clorazepate. Phenobarbital concentrations may increase shortly after clorazepate therapy is begun if the two drugs are given simultaneously. Decreased phenobarbital dosing may be indicated. Clorazepate concentrations may decrease several months after combination therapy. Clinically important drug interactions resulting from chronic diazepam therapy have not been reported.

CLINICAL USE. Diazepam is the first drug of choice for status epilepticus in both the dog and the cat and is the second drug of choice for long-term control of seizures in the cat. Clorazepate can be used (generally in combination with phenobarbital) for long-term control in dogs. The therapeutic range of benzodiazepines (including metabolites) in dogs has been extrapolated from people and does not reflect combination therapy. Interactions between phenobarbital and clorazepate may necessitate dose modification. Monitoring (diazepam and its metabolites) is available through some laboratories. Since drug half-life is short, both peak and trough samples are recommended. The incidence of adverse affects may be reduced by using a smaller dose at 8-hour intervals.

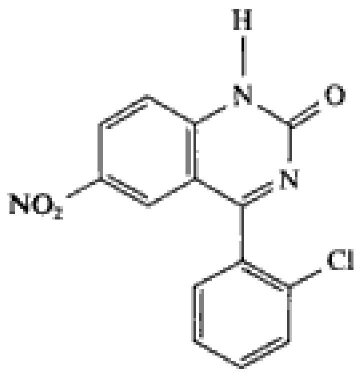
USE IN TREATMENT OF STATUS EPILEPTICUS. Because of the efficacy and rapidity of its action and lack of toxicity, the IV use of diazepam is the drug of choice for control of status epilepticus in humans (de Angelis 1979). In the dog, diazepam is rapidly metabolized and tolerance to its antiepileptic effect develops rapidly (Frey 1986); thus it is not satisfactory for continued treatment and/or control of epilepsy. Diazepam is best suited and is the drug of choice for emergency IV use in control of status epilepticus (Frey and Löscher 1985). IV diazepam may be rivaled by clonazepam, a relatively new benzodiazepine, because tolerance to its anticonvulsant effects develops more slowly.

The onset of more than one seizure per hour is a medical emergency (Cunningham 1984). To terminate the seizures in dogs, various methods of administration have been recommended. Diazepam has been recommended in an IV dose of 5-20 mg and in an IV dose of

0.5-1 mg/kg (Frey and Löscher 1985). Because it has a short half-life, dosing may have to be repeated once or twice during the first 2 hours to stabilize the dog (Cunningham 1984). A comparable IM dose may be given for longer stabilization. Alternatively, IV phenobarbital may be given. If the seizures are not subdued by diazepam, it may be necessary to give a general anesthetic (see discussion below on pentobarbital). Another procedure for treatment of status epilepticus has been described by Averill (1970). A dose of 5 mg diazepam is administered slowly by the IV route. In the event this dose level does not abolish the seizure in 1-2 minutes, the dose is repeated. If a response has not occurred following the second dose of the drug, IV pentobarbital sodium (16.5 mg/kg) is slowly administered. Patients that respond to the first and/or second dosages of diazepam are carefully monitored, and if status epilepticus returns in 2-4 hours after the initial treatment, the regimen is repeated. An oral anticonvulsant is started as soon as seizures are abolished.

Diazepam is used in control of epileptic disorders in the cat regardless of etiology (Kay 1975). Generally, an IV dose (5-10 mg) is given to effect. A dose as high as 20 mg may be necessary; if high dosages are used, they must be injected slowly. The procedure commonly followed is to administer 2-10 mg IV and then wait 10 minutes. In the event seizures persist, Kay (1975) recommends IV administration of phenobarbital sodium (5-60 mg). Caution must be taken not to oversedate or depress the animal when these drugs are administered close together. Should the animal manifest refractoriness to diazepam and phenobarbital, pentobarbital anesthesia is then carefully administered to effect (see discussion below). Once the seizures have been brought under control, oral anticonvulsant therapy should be initiated. Phenobarbital (8-32 mg) is given orally 2-3 times daily; diazepam may be used in place of phenobarbital in animals that react unfavorably to barbiturate therapy. Diazepam is given orally in doses of 2-5 mg 2 or 3 times daily. Phenobarbital dosages may be adjusted by increasing or decreasing in 4-8 mg increments; diazepam may be increased or decreased in increments of 2 mg (Kay 1975).

CLONAZEPAM. *Clonazepam,* USP (Clonopin), is a benzodiazepine derivative and is chemically 5-(*o*-chlorophenyl)-1,3-dihydro-7-nitro-2*H*-1,4-benzodiazepin-2-one (Fig. 16.2). It is more potent than diazepam and is used only in the emergency treatment of status epilepticus in the dog (Frey and Löscher 1985). Clonazepam is given IV in a dose of 0.05-0.2 mg/kg. Accumulation occurs upon continued administration. However, tolerance develops due to hepatic enzyme induction within days to weeks after administration. Consequently, clonazepam, like diazepam, is unsatisfactory in long-term control of epilepsy.



Clonazepam

FIG. 16.2

Bromide

MECHANISM OF ACTION. Bromide is an old anticonvulsant and sedative whose mechanism of action is not completely understood (Wuth 1927). Replacement of negatively charged chloride with bromide has been hypothesized as the mechanism; the neuron becomes hyperpolarized (i.e., the RMP becomes more negative in relation to the threshold potential). The anticonvulsant effects of bromide correlate with plasma concentration (Grewal 1954). Bromide is available in several salt forms (sodium, potassium, and ammonia). Differences among the products reflect solubility (thus ease of compounding) in water and the amount of bromide per gram of compound (i.e., more bromide in NaBr than in KBr because Na weighs less than K).

DISPOSITION. The pharmacokinetics of bromide has not been well established. The half-life in dogs may be 24 days. Steady-state concentrations are not achieved for 3-6 months. Distribution is to extracellular fluid. Bromide is eliminated slowly (perhaps due to marked reabsorption) in the kidney. Its rate of elimination changes with salt administration. Increased dietary salt will increase the rate of elimination of bromide (perhaps due to preferential reabsorption?), and decreased salt will cause the opposite (Rauws and van Logeten 1975; Shaw et al. 1996). Bromide has not been studied in cats.

SIDE EFFECTS. Adverse reactions to bromide are usually neurological and include ataxia, grogginess, and sedation (Nichols et al. 1996; Yohn et al. 1992). Skin reactions have been reported and are probably more likely in patients that already have skin disease (e.g., flea bite dermatitis). Vomiting is not unusual and probably reflects the hyperosmolality of the drug. In the case of acute bromide toxicity, NaCl administration (0.9% NaCl) is the treatment of choice. Hepatotoxicity is not a concern with this drug.

CLINICAL USE. In humans, bromide has been used to treat intractable seizures in pediatric patients (Woody 1990; Podell and Fenner 1993). In dogs bromide is most commonly used as an "add-on" anticonvulsant in epileptic patients who have not sufficiently responded to or cannot tolerate phenobarbital (especially due to hepatotoxicity) (Pearce 1990; Schwarze-Porsche and Jurgens 1991; Boothe 1998). Because steady state may require 2-3 months, a loading dose is recommended to achieve therapeutic concentrations more rapidly. Therapeutic efficacy cannot be fully evaluated for several months following the start of administration unless a loading dose is administered. The loading dose should establish steady-state concentrations immediately and is based on a volume of distribution of 0.3 L/kg and a target concentration of 1.5 mg/mL: 450-600 mg/kg over 5 days plus the recommended daily dose. The 5-day duration of dosing reduces the likelihood of emesis postadministration. Plasma drug levels should be measured after loading to evaluate the efficacy of the loading dose.

Bromide is not available in a medicine grade and must be purchased from a chemical company (request ACS grade). Some companies will not sell the chemical if a medicinal use is planned. Application to the FDA for regulatory discretion will avoid illegalities associated with the use of bromide for seizure control.

Bromide can be mixed to a convenient concentration in water (administer 44 mg/kg every 24 hr orally) or administered in a gelatin capsule. Twice daily administration may be necessary because of the bitter taste and its tendency to induce vomition. Its primary indication is probably in combination with phenobarbital in refractory epileptics. Decreasing phenobarbital doses may be possible once therapeutic concentrations have been reached and may be indicated if animals become groggy or ataxic. Recommended target ranges are controversial and depend on whether phenobarbital is also being given. Our laboratory uses 0.8-2 mg/mL if in combination with phenobarbital or, if sole agent, up to 3 mg/mL.

Pentobarbital Sodium. *Pentobarbital Sodium,* USP (Nembutal sodium, Pentobarbitone sodium, Sagatal, Napental), administered IV is considered the most efficacious procedure for abolishing refractory status epilepticus in the dog (Redding 1969). Pentobarbital is also valuable in terminating refractory status epilepticus in other species. Extreme care, however, is required not to overdose. The dose of the anesthetic varies considerably from one animal within a species to the next. Consequently, pentobarbital is carefully given to effect.

In humans, tonic-clonic status epilepticus that is refractory to phenobarbital, phenytoin, and diazepam may respond to an IV infusion of pentobarbital given continuously for several days. Then it is discontinued, and oral phenobarbital along with other anticonvulsants is advocated to control recurring epileptic episodes. Respiratory and myocardial depression necessitate EEG and cardiopulmonary monitoring and support (Jagoda and Riggio 1993).

Miscellaneous Antiepileptics. Other antiepileptic agents, infrequently used in veterinary medicine, are available in human medicine for treatment of various CNS seizure disorders. Their safety and effectiveness in clinical veterinary medicine have not been determined in most instances. Additionally, the biologic half-lives for some (e.g., valproic acid, carbamazepine) of these compounds are too short in the dog to permit maintenance of adequate drug concentrations in plasma and the CNS (Frey 1986). Valproic acid (valproate) and carbamazepine have found established places in treatment of human seizure disorders (Eadie 1991). The benzodiazepine derivatives, primarily clonazepam, have proven useful and effective in treatment of human epilepsy. The use of anticonvulsants such as paramethadione, aloxidone, and troxidone (of the oxazolidinedione family) have declined extensively for control and/or treatment of epilepsy in humans. They have been essentially replaced by the less toxic and more effective succinimide derivatives (notably ethosuximide) and more recently by clonazepam and valproate. New hydantoins (albutoin, methoin) have been synthesized in an attempt to find a better antiepileptic than phenytoin; to date this effort has been unsuccessful.

Drugs Contraindicated in Epileptic Patients. Reserpine and phenothiazine and butyrophenone tranquilizers are contraindicated in epileptic patients because they can induce seizures. Other drugs capable of inducing seizures in selected patients include metaclopramide and fluorinated quinolones. Morphine sulfate and related compounds as well as CNS stimulants such as the methylxanthines should be avoided. Chloramphenicol also activates the CNS and should not be used in dogs known to be subject to epileptiform seizures.

CNS STIMULANTS. A large number of drugs possess the ability to stimulate the CNS. Stimulant, or convulsant, drugs vary markedly in their total pharmacologic action. Some can be used for therapeutic stimulation within narrow limits of dosage; others are only poisons. Some, such as ephedrine, influence the function of the CNS only secondarily while primarily affecting another system of the body. Toxic drugs, such as nicotine and strychnine, stimulate the CNS as a manifestation of poisoning. Many of these are considered poisons and are discussed accordingly.

Some drugs affecting the CNS have a specific action that limits their clinical application. Apomorphine hydrochloride, for example, stimulates the emetic center in the medulla more than other parts of the brain, so it is used clinically to induce emesis in species sensitive to its action. Stimulants of the CNS such as caffeine and other methylxanthines used by humans stimulate sensory areas of the brain to combat mental fatigue. Compared to other stimulants, the methylxanthines have been less important in veterinary medicine. However, the discovery of the adenosine receptors should increase interest in use of methylxanthines such as theophylline.

Other drugs that stimulate the CNS act directly on the respiratory center to counteract respiratory collapse. These are employed in treatment of barbiturate poisoning, drowning, neonatal asphyxia, heat or lightning shock, and threatened respiratory collapse during anesthesia. Doxapram is an example.

The term "respiratory analeptic" refers to drugs that stimulate a depressed respiratory center to produce increased respiratory exchange. In addition to restoring respiratory function, analeptics may restore depressed vasomotor and cerebral functions, including consciousness (Wang and Ward 1977).

Drugs used for analeptic effect, with the exception of carbon dioxide, exert an arousal effect characterized by a partial return of consciousness of the patient. Animals often do not return to a state of normal cerebration or locomotion. Animals may become traumatized during this stimulation period. The period of stimulation is brief. Generally, the best therapy for respiratory paralysis is to apply artificial ventilation using oxygen. The introduction of safer and much more specific antagonists such as naloxone for the opioid agents and yohimbine for α agonists and the discovery of other compounds with specific antagonist activity have increased the number of drugs available to treat selected causes of respiratory depression.

Doxapram Hydrochloride. *Doxapram Hydrochloride*, USP (Dopram), is approved by the FDA for use in the dog, cat, and horse. It has not been approved for use in animals intended for human consumption. Chemically, doxapram is 1-ethyl-4-(2-morpholinoethyl)-3,3-diphenyl-2-pyrrolidinone hydrochloride.

PHARMACOLOGIC CONSIDERATIONS. Doxapram is primarily used to stimulate respiratory activity in the postanesthetic, recovery period. Doxapram directly stimulates chemoreceptors of the carotid and aortic regions (Wang and Ward 1977). It may also stimulate the medullary respiratory center (Severinghaus et al. 1976). Tidal volume increases as a result. Stimulation of other portions of the CNS occurs only when high dose levels are used. Convulsions or alterations in electroencephalographic (EEG) patterns are not seen with therapeutic levels (Soma and Kenny 1967). The convulsant dose of doxapram is 70-75 times the dose that stimulates respiratory center activity.

Doxapram is considered superior to all combinations of analeptic agents evaluated. The respiratory minute volume is increased 200% within 1 minute after administration of doxapram in the dog (Klemm 1966). When doxapram (2 mg/kg) is administered intravenously, the change in expired minute volume is marked and rapid (Soma and Kenny 1967). The ventilatory and cardiovascular stimulatory effects occur within one circulation time of the drug. The initial marked increase in expired minute volume is due to an increase in tidal volume and respiration rate. However, the increase in tidal volume is not maintained and diminishes in 5-6 minutes. Overall improvement in ventilation is reflected by changes in the acid-base status of the blood as well as in the oxygen tension of arterial blood.

The pressor response of doxapram occurs rapidly and concurrently with respiratory effects (Soma and Kenny 1967) and is believed to be mediated through activation of the sympathetic nervous system. An arterial hypotensive effect of brief duration occurs after IV administration of a large dose (4 mg/kg); this effect does not occur when a dose of 2 mg/kg or less is administered. The pressor and respiratory responses occur when the dose of doxapram is not higher than 2 mg/kg (Soma and Kenny 1967).

Studies in cats anesthetized with pentobarbital sodium have determined the effects of bilateral and unilateral pneumotaxic center ablation upon doxapram-induced respiratory changes (St. John et al. 1973). In these ablated animal preparations, doxapram stimulation of respiration caused only minor changes in tidal volume, but frequency of respiratory activity increased. IV doses of doxapram (1-2.5 mg/kg) were adequate to stimulate effects through peripheral chemoreceptor and medullary respiratory area activation. Doxapram-induced stimulatory influences arising from one or both these areas (i.e., chemoreceptor and/or medullary respiratory center) are integrated by the pontile pneumotaxic center.

Doxapram has also been experimentally used in the pig, rabbit, sheep, and chicken; sheep and rabbits appear to be far less sensitive than other species to effects of analeptic agents (Beretta et al. 1973). Although there are variations in the degree of responses produced by different analeptics in various species, doxapram, when used alone or in combination with other analeptics, usually elicits marked improvement in respiratory activity.

CLINICAL USE. Use of doxapram in clinical practice is specified for reversal of central respiratory depression from barbiturates and inhalant anesthetics. In neonatal puppies, doxapram can be administered subcutaneously or sublingually (topically on mucous membrane) at a total dose of 1-5 mg. It may also be administered in the umbilical veins of puppies at the time of birth to stimulate respiration. It may be given to neonatal kittens subcutaneously or sublingually (topically on mucous membrane) at a total dose of 1-2 mg.

Table 16.2 lists some of the clinical uses and recommended IV doses of doxapram. Doses of doxapram can be repeated within 15-20 minutes and should be decreased or increased to achieve the desired effect. Efficacy decreases with subsequent doses (Jensen and Klemm 1967).

Experimentally, IV doxapram (1 mg/kg) is capable of antagonizing subcutaneous (SC) xylazine (3 mg/kg) in the dog (Dendi 1979). Immediately after administration of doxapram, dogs are able to walk without difficulty. Dogs given IV xylazine (2.2 mg/kg), followed by IV doxapram (5.5 mg/kg) about 15 minutes later, were able to walk within 3-5 minutes (Short et al. 1982). Those treated with normal saline required 30-120 minutes to recover from xylazine. To reverse the sedative action of 1.1 mg/kg IV xylazine in the dog, an IV dose

Table 16.2—Clinical uses and recommended IV doses of doxapram

Species	Dose (mg/kg)	Clinical use
Dog and cat	5.5–11	Barbiturate depression
Dog and cat	1.1	Depression from inhalant anesthetics
Horse	0.55	Depression from chloral hydrate and/or pentobarbital
Horse	0.44	Depression from inhalant anesthetics

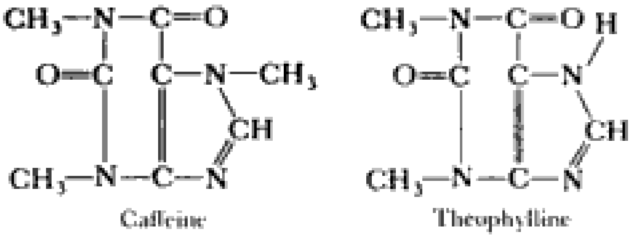


FIG. 16.3

of 1.1 mg/kg doxapram is sufficient in most cases (Sodikoff 1982).

In the dog, IV doxapram (5.5 mg/kg) administered 15-20 minutes after IM acepromazine (1.1 mg/kg) induces walking within 2-10 minutes in 5 of 6 animals studied; the 6th dog began to walk after 30 minutes (Short et al. 1982). In control dogs treated with normal saline, more than 2 hours elapsed before any of the animals given acepromazine could begin walking.

Doxapram is the most effective antagonist of thiopental-acepromazine-anesthetized dogs (Hatch et al. 1985b). However, yohimbine is the most effective antagonist of thiopental anesthesia in xylazine-treated dogs. Droperidol-fentanyl-pentobarbital anesthesia in the dog is best reversed by IV doxapram (5 mg/kg) plus a IV dose of naloxone (1 mg/kg) (Hatch et al. 1986).

In the horse, clinical evaluation of doxapram (0.55 mg/kg) as a respiratory stimulant was conducted during and after general anesthesia with IV injections of chloral hydrate alone and chloral hydrate in combination with pentobarbital and magnesium sulfate (Short and Cloyd 1970). The arousal time was reduced; respiratory volume and rate increased immediately following administration of the drug. No toxic or adverse effects were noted. A clinical evaluation of doxapram (0.46 mg/kg) in the horse during and after general anesthesia with halothane and methoxyflurane indicated that doxapram improved ventilation in horses anesthetized with halothane soon after administration of the drug (Short and Cloyd 1970). However, studies in humans revealed that halothane anesthesia virtually abolishes the respiratory stimulant effect of doxapram (Knill and Gelb 1978). Previous studies indicated that peripheral chemoreceptor-mediated reflexes are relatively durable and resistant to depressant effects of anesthetic agents. However, work on the hypoxic chemoreflex in dogs anesthetized with halothane, isoflurane, or enflurane contradicts this viewpoint (Weiskopf et al. 1974; Hirshman et al. 1977). Additional work is needed to reexamine the pharmacologic action of doxapram in horses and other species anesthetized with halothane and possibly with other inhalant anesthetics.

Doxapram (100-160 mg) is used intravenously to facilitate endoscopic examination of laryngeal motion in the horse; hyperpnea is induced in about 20 seconds following injection of the drug (Marks 1973). Hypoxic respiratory activity induced by an etorphine-acepromazine mixture is only partially reversed by doxapram, so there is no overall advantage in using doxapram to reverse etorphine-induced hypoxia (Hillidge 1976).

In cattle, IV doxapram (0.46-0.6 mg/kg) is capable of reversing the action of IV xylazine (0.2 mg/kg) (Dendi and Parada 1981). IV doxapram (1 mg/kg) followed immediately by IV 4-aminopyridine (0.3 mg/kg) has proven to be effective in antagonizing large IM doses of xylazine (0.3-0.4 mg/kg) in steers (Zahner et al. 1984).

Methylxanthine Derivatives. Caffeine, theophylline, and theobromine are closely related alkaloids, all containing the xanthine nucleus (Fig. 16.3). Theobromine is of interest primarily as a toxicant. These drugs have important pharmacologic properties in addition to CNS stimulation.

Caffeine is found in coffee beans to the extent of about 1%. Theophylline and caffeine are present in tea leaves to around 3%. The methylxanthine compounds affect the same organs but to a varying degree. They all stimulate the CNS, dilate the coronary blood vessels, and promote diuresis. However, caffeine is primarily a CNS stimulant. Theophylline is better for promoting diuresis and relaxation of bronchial smooth muscle.

CAFFEINE. *Caffeine,* USP, is primarily used in human medicine. Discovery of more potent CNS stimulants has essentially made caffeine obsolete as an analeptic agent. Therapeutic use of caffeine is limited in animals. It has been used experimentally as a test of hepatic function since its plasma elimination reflects activity of drug-metabolizing enzymes in the liver (Boothe et al. 1994).

ACTION. Caffeine increases irritability of the sensory cortex, which results in increased mental alertness. Caffeine is a potent cerebral stimulant that may superimpose exceptional muscular activity over fatigue and temporarily increase capacity for muscular work. Large doses cause an increased motor activity that may lead to exaggerated responses to normal stimuli.

Caffeine will stimulate respiratory centers directly when they are depressed by CNS depressant drugs. It has been suggested that caffeine may act by rendering respiratory centers more sensitive to carbon dioxide. The mechanism of action of the methylxanthines is controversial. Proposed mechanisms include translocation of intracellular calcium, accumulation of cyclic nucleotides (e.g., cyclic adenosine 3′,5′-monophosphate, or cAMP), and blockade of adenosine receptors. The last may be the most important. There are known cellular mechanisms through which methylxanthines may cause their varied pharmacologic effects. Caffeine and other methylxanthines inhibit phosphodiesterase, an enzyme that degrades cAMP. Cardiac acceleration (from β-adrenergic stimulation) occurs with an increase in cAMP. Arrhythmia may be induced following administration of caffeine. Drinking one cup of coffee can induce arrhythmia in some human subjects.

METABOLISM. Caffeine is readily absorbed from the digestive tract or from the site of injection in small animals. It is partially demethylated to theophylline and theobromine and other metabolites before it is excreted in urine. In dogs, caffeine distributes rapidly to a volume of 0.8 L/kg and is minimally (83% ± 16% at 20 μg/mL) bound to serum proteins. It is characterized by a clearance of 2.05 ± 0.1 mL/min/kg and an elimination half-life of 255 ± 76 minutes (Boothe et al. 1994). Liver disease results in decreased clearance and an increased elimination half-life (750 ± 450 hr) (Boothe et al. 1994).

In the horse, following oral administration of 3 g caffeine, about 3% of the dose is eliminated unaltered in urine during the first 24 hours (Tobin et al. 1979). There is no evidence that caffeine is conjugated in horses as either glucuronides or arylsulfates. However, traces of theobromine are found in horse urine for up to 10 days after a dose of caffeine. Theobromine is found in sufficient quantities to make urine test positive for caffeine. Use of caffeine in the competitive racing animal is illegal.

TOXICITY. Caffeine has a wide margin of safety. An excessive dose can produce convulsions, but the amount is of such magnitude as to render clinical occurrence unlikely. At first the convulsions are epileptiform, but later they become tonic as the effect of caffeine descends to the spinal cord. The convulsive effect may be counteracted by administration of a barbiturate. A lethal dose of caffeine administered parenterally in the dog and cat is 110-175 mg/kg and 80-150 mg/kg, respectively.

AMINOPHYLLINE. *Aminophylline,* USP (theophylline ethylenediamine), is one of the more soluble salt forms of theophylline. It has a brief but potent action in stimulating diuresis. In laboratory animals, theophylline has been shown to dilate coronary blood vessels. This effect is highly beneficial because the increased blood flow that it brings to the myocardium increases mechanical efficiency of the heart. Theophylline is an inhibitor of phosphodiesterase, an enzyme that destroys cAMP.

In addition to inhibitory action upon phosphodiesterase, the methylxanthines block the action of adenosine (A_1 and A_2 receptors; also referred to in some literature sources as purinoceptors or P_1 and P_2 receptors) in a competitive manner (Kulkarni and Mehta 1984). Adenosine is believed to be a neuromodulator in the brain, because it modifies adrenergic neurotransmission by inhibiting norepinephrine release in various tissues. It is also recognized as having sedative and anticonvulsant activity. Consequently, the effects of adenosine are opposite to those of theophylline or caffeine.

The CNS depressant activity of adenosine is believed to be potentiated by diazepam and related benzodiazepines; e.g., it has been suggested that this action is due to an inhibition of adenosine uptake in the brain. Purine nucleosides related to adenosine (e.g., inosine and hypoxanthine) may be endogenous ligands for benzodiazepines. Thus, benzodiazepines such as diazepam may exert their pharmacologic actions by displacement or by mimicking these ligands. In humans, aminophylline is a potent antagonist to the sedative and CNS depressant actions of diazepam (Arvidsson et al. 1984; Marrosu et al. 1985).

Interestingly, morphine enhances the release or efflux of adenosine from brain tissue. It is believed that some of the action of morphine may be mediated through adenosine receptors (purinoceptors) as a result of adenosine release. Methylxanthines, adenosine antagonists, have been reported to antagonize the inhibitory effect of morphine upon release of acetylcholine (ACh) and other NTs (Kulkarni and Mehta 1984). Additionally, morphine-induced deaths and inhibition of electrically induced contractions of the guinea pig ileum can be antagonized by theophylline. Also, pretreatment with naloxone (an antagonist of morphine) potentiates the toxicity of theophylline.

TOXICITY. Generally, large doses of methylxanthines are required to produce toxic effects in animals. There is no specific antidote for the methylxanthines.

Compared to the dog, the horse appears to be more sensitive to the CNS action of theophylline and other methylxanthine derivatives. Side effects such as agitation, tremors, hyperesthesia, sweating, polypnea, and tachycardia occur in the horse after an IV dose of 15 mg/kg theophylline (Errecalde et al. 1985). CNS effects are moderate at 10 mg/kg and mild or absent at 5 mg/kg following its IV administration in horses. A plasma theophylline concentration of 15 mg/mL is considered to be the upper safe limit in horses (Errecalde et al. 1985).

A clinical case of aminophylline toxicity occurred in swine from the inadvertent packaging of this product by a manufacturer. The owner believed he was administering piperazine adipate to his pigs for anthelmintic purposes. After administering the recommended dose, 5 out of a total of 8 pigs died. Some of the clinical signs of the survivors were intense excitement and incoordination. They staggered as they walked and then lay down to thrash or paddle their feet.

CLINICAL USE. Methylxanthines are rarely used for their CNS stimulant activity in animals. Their effects as CNS stimulants are of clinical interest primarily as a sign of toxicity when used therapeutically (e.g., as bronchodilators) or diagnostically (e.g., caffeine as a test of hepatic function).

Antagonists

4-AMINOPYRIDINE. *4-Aminopyridine* (4-AP) has potent CNS stimulant activity. In overdosages it is a convulsive agent. 4-AP has been used clinically in humans for several years in Europe as an antagonist to *d*-tubocurarine. It appears to facilitate neuronal Ca^{++} uptake and enhance ACh release in its antagonism of *d*-tubocurarine and other nondepolarizing skeletal muscle relaxants. In addition to its probable action upon Ca^{++}, 4-AP produces a selective block of K^+ channels in excitable membranes (Glover 1982).

4-AP is also effective in reversal of intercostal and diaphragmatic paralysis induced by aminoglycoside antibiotics, such as neomycin and dihydrostreptomycin. Because of its cholinergic activity involving the neuromuscular junction, 4-AP has been used effectively in treatment of *Clostridium botulinum* paralysis.

The action of 4-AP upon the CNS is not well understood. A number of NTs apparently are released by it in the brain. Consequently, 4-AP is capable of antagonizing several CNS depressants partially or completely.

In humans, 4-AP in the same IV dose (0.3 mg/kg) that safely antagonizes effects of *d*-tubocurarine and pancuronium increases the rate of recovery from diazepam-ketamine anesthesia (Agoston et al. 1980). In veterinary medicine, 4-AP appears to have considerable potential as an antagonistic agent for accelerating recovery from a number of CNS depressants.

Studies in the dog have revealed that IV 4-AP (0.5 mg/kg) combined with naloxone (0.04 mg/kg) will immediately reverse the neuroleptanalgesic action of a droperidol-fentanyl combination (Booth et al. 1982). Moreover, it is effective in combination with yohimbine as an antagonist of xylazine sedation in the dog (Hatch et al. 1982). IV 4-AP (0.3 mg/kg) plus IV yohimbine (0.125 mg/kg) antagonizes the standard clinical IM dose of xylazine (2.2 mg/kg) as well as the 5 times overdose of 11 mg/kg. The combination of 4-AP and yohimbine is also effective in reversal of xylazine used with a large dose of atropine (Wallner et al. 1982) and in reversal of acepromazine-xylazine in the dog (Cronin et al. 1983).

In the cat, IV 4-AP (0.6 mg/kg) plus IV yohimbine (0.25 mg/kg) appears to be a safe and effective partial antagonist of IM ketamine (20 mg/kg) anesthesia (Hatch et al. 1983a). Cats pretreated with IM acepromazine (0.25 mg/kg) and anesthetized by IV pentobarbital (16.8 ± 3.8 mg/kg) can be aroused by an IV combination of 4-AP (0.5 mg/kg) and yohimbine (0.4 mg/kg); yohimbine enhances the antagonistic action of 4-AP (Hatch et al. 1984a).

Thiopental anesthesia is antagonized rapidly and permanently in atropinized (IM dose of 0.05 mg/kg) cats pretreated with IM xylazine (2.2 mg/kg) and given IV 4-AP (0.15 mg/kg) with IV yohimbine (0.125 mg/kg) (Hatch et al. 1984b). Meperidine-acepromazine-pentobarbital anesthesia can be smoothly and permanently reversed within minutes with IV 4-AP (0.5 mg/kg) plus IV yohimbine (0.4 mg/kg) in the cat (Hatch et al. 1984c).

In cattle, the combination of 4-AP plus doxapram is considered the most efficacious antagonist of xylazine sedation (see discussion in this chapter on doxapram). The pharmacokinetic characteristics of 4-AP have been determined in cattle (Kitzman et al. 1984b). After an IV injection of 0.3 mg/kg, the distribution half-life is 12 minutes and the elimination half-life is 129 minutes.

In the horse, 4-AP alone is the best antagonist of xylazine-ketamine anesthesia (Kitzman et al. 1984c). An IV dose of 0.2 mg/kg reverses IV xylazine (1.1 mg/kg) plus ketamine (2.2 mg/kg) anesthesia. The pharmacokinetic parameters of 4-AP have been determined in horses (Hendricks et al. 1984). After a bolus IV injection of 0.2 mg/kg, the distribution half-life is 7 minutes and the elimination half-life is 259 minutes. The elimination half-life of 4-AP in the horse is twice that of cattle (Kitzman et al. 1984b). Also, the horse has a longer elimination half-life than the dog (2.1 hr, Rupp et al. 1983) and the human (3.6 hr, Uges et al. 1982). From a toxicity standpoint, the horse appears to be quite sensitive to 4-AP; the lethal dose is estimated at 2-3 mg/kg (Ray et al. 1978). Methodology for detecting 4-AP in horse plasma as low as 25 ng/mL has been developed (Hendricks et al. 1984).

In the goat, IM xylazine (0.5 mg/kg) administered at 2.5 times the standard dosage for this species along with 0.5 mg/kg atropine is antagonized by an IV dose of 4-AP (0.3 mg/kg) plus yohimbine (0.125 mg/kg) (Jensen et al. 1983). Also, 4-AP plus yohimbine has been used to antagonize the combination of xylazine-atropine in white-tailed deer, North American otters, striped hyenas, and giraffes (Jensen et al. 1983).

In moose *(Alces alces)*, mule deer *(Odocoileus hemionus)*, and white-tailed deer *(Odocoileus virginianus)*, successive IV administration of 4-AP (0.26 mg/kg, moose; 0.29 mg/kg, deer) plus yohimbine (0.15 mg/kg) markedly enhances the speed of recovery from xylazine-induced immobilization (Renecker and Olsen 1985).

4-AP has not been approved for use in animals by the FDA. Studies on its safety and efficacy will first need to be conducted, as well as tissue residue studies in food-producing animals.

YOHIMBINE HYDROCHLORIDE. Yohimbine hydrochloride is an old drug alleged to have aphrodisiac characteristics. An indolealkylamine alkaloid, it is found in rauwolfia root and is structurally similar to reserpine. It is a competitive α_2 antagonist. It disappeared from clinical use and became an obsolete drug many years ago. However, yohimbine is again serving as an important pharmacologic tool as a preferred α_2-adrenergic blocking agent (Starke et al. 1975).

In the 1960s, a number of investigators proposed that activation of central α-adrenergic receptors induces sedation in sleep. Agents such as xylazine and its related derivative clonidine induced sedation and/or sleep. It was learned that yohimbine could antagonize the sedative or sleeplike effects of clonidine in mice and chickens (Delbarre and Schmitt 1973). Moreover, it was discovered that yohimbine antagonized the analgesic activity of xylazine, an α-sympathomimetic agent, in the rat (Schmitt et al. 1974). The sedative, sleep, and analgesic actions produced by xylazine were attributed to its agonist effect upon α_2-adrenergic receptors in the brain. Consequently, yohimbine, piperoxan, and tolazoline, which preferentially block α_2-adrenergic receptors, are capable of antagonizing the actions of xylazine and clonidine. Additionally, yohimbine partially antagonizes other CNS depressants that affect synaptic mechanisms, such as barbiturates (Hatch 1973), ketamine (Hatch and Ruch 1974), and benzodiazepines (Lang and Gershon 1963). Thus, by binding on the same preferential, or primary (α_2-adrenergic), and secondary (cholinergic, serotonergic, GABAergic) receptor sites as some of the CNS depressants, yohimbine serves as an effective antagonist of a number of CNS agents. Xylazine, in particular, is antagonized quite effectively by yohimbine.

In the dog, yohimbine is more effective than 4-AP or doxapram in antagonizing the effects of xylazine (Hatch et al. 1985a). An IV dose (0.2 mg/kg) reverses the effect of a standard IM dose of 2.2 mg/kg xylazine. IM xylazine (11 mg/kg) 5 times the standard dose can be antagonized rapidly and completely by an IV dose of 0.4 mg/kg yohimbine (Hatch et al. 1985a). An IV combination of yohimbine (0.25 mg/kg) and 4-AP (0.5 mg/kg) can reverse pentobarbital anesthesia in atropinized dogs that are given IM xylazine (2.2 mg/kg) premedication; this dose of xylazine decreases the required dosage of pentobarbital about 80% (Hatch et al. 1983b). Hsu (1985) also observed that xylazine-pentobarbital anesthesia can be antagonized by yohimbine. Yohimbine also antagonizes the cardiovascular effects of jing songling, a xylazine analog (Hsu et al. 1985a).

The hypertensive, hypotensive, and cardiac slowing actions of IV xylazine (1 mg/kg) are antagonized in the dog by an IV dose of 0.1 mg/kg yohimbine (Hsu et al. 1985a). Yohimbine, administered as a single IV dose at 0.1 mg/kg in dogs anesthetized with pentobarbital, increases systolic arterial pressure, heart rate, and cardiac performance (Andrejak et al. 1983).

In cats treated with IM acepromazine (0.25 mg/kg), an IV combination of yohimbine (0.4 mg/kg) plus 4-AP (0.5 mg/kg) is the most effective antagonist in reversal of anesthesia induced by pentobarbital (Hatch et al. 1984a). Yohimbine enhances the antagonistic actions of 4-AP. In cats anesthetized with pentobarbital and premedicated with IM xylazine (2.2 mg/kg), IV yohimbine (0.4 mg/kg) is effective by itself. Yohimbine and 4-AP will partially reverse the anesthesia, but not the cataplexy, associated with ketamine (Hatch et al. 1983a). Jensen (1985) has reported treating an overdose of xylazine in a cat with yohimbine. An IV injection of 0.1 mg/kg yohimbine exerted its effect in about 2 minutes; the cat regained consciousness and was clinically normal within 10 minutes.

In the pony, IV yohimbine (0.1 mg/kg) reverses anesthesia induced by a combination of xylazine and thiopental (Hsu et al. 1985b). Also, IV yohimbine (0.1 mg/kg) is effective in reversing anesthesia induced by xylazine and pentobarbital (McGruder and Hsu 1985).

Yohimbine has been used to reverse the immobilizing effects of xylazine and xylazine-ketamine combinations in exotic species. In the African elephant tranquilized with ketamine (0.3 mg/kg) and xylazine (0.1 mg/kg), arousal occurs within 2-3 minutes after an IV injection of 0.125 mg/kg yohimbine (Jacobson and Kollias 1984). In African elephants, dromedary camels, sika deer, Père David deer, Barbary sheep, and springbok immobilized with xylazine or xylazine-ketamine, IV yohimbine (0.125 mg/kg) alone or in combination with doxapram (0.4 mg/kg) produces standing within 4 minutes after injection.

In mule deer, ketamine (9.2 mg/kg) and xylazine (0.73 mg/kg) anesthesia have been reversed in an average of 8.2 minutes by IV yohimbine (0.125 mg/kg); although unspecified, administration of ketamine and xylazine was probably by the IM route (Gullet 1984). Mule deer given xylazine alone at 0.75-1 mg/kg regain ambulatory ability 3 minutes or less after administration of IV yohimbine (0.125 mg/kg). Yohimbine has also been used in a few elk and bighorn sheep. According to Gullet (1984), the drug has potential for increasing anesthetic safety and human handler safety and for saving wildlife agencies hundreds of hours of labor.

Pretreatment with IV yohimbine (0.1 mg/kg) prevents sedation, bradycardia, sinus arrhythmia, and arterial hypertension induced by amitraz (Hsu et al. 1986). Amitraz apparently has α_2-adrenergic agonist activity.

Use of yohimbine in animals has not been approved by the FDA. Before it can be approved for use in food-producing animals, tissue residue studies must be conducted.

TOLAZOLINE HYDROCHLORIDE. *Tolazoline Hydrochloride*, USP (Priscoline), is chemically 2-benzyl-2-imidazoline. It has a wide range of pharmacologic effects, including adrenergic blocking, sympathomimetic, antihistaminic, and antihypertensive actions. Tolazoline has been used primarily in human medicine.

Since tolazoline is an α_2-adrenergic blocking agent, it has been used in the reversal of xylazine sedation. In the dog, IV tolazoline (5 mg/kg) reverses IV xylazine (1.1 mg/kg) (Tranquilli et al. 1984). Animals anesthetized with xylazine-halothane require increased concentration of halothane after tolazoline blocks the action of xylazine.

In sheep, IV tolazoline (2 mg/kg) antagonizes 2-4 times the recommended dose of xylazine (Hsu et al. 1987). It reverses the bradycardia and tachypnea induced by xylazine.

Tolazoline (0.5 mg/kg) by the IV route has been used to antagonize xylazine-ketamine immobilization of the juvenile African elephant (Allen 1986). Its administration induces rapid arousal and return to mobility.

In dogs, IV tolazoline (5 mg/kg) antagonizes the apparent α_2-adrenergic agonist action of amitraz (Hsu et al. 1986).

Tolazoline is less potent than yohimbine as an α_2-adrenergic blocking agent. It has not been approved by the FDA for use in animals. Data are needed to determine its safety and efficacy as an antagonist of xylazine and of other drugs that have α_2-adrenergic agonist activity.

DRUGS AFFECTING ANIMAL BEHAVIOR

DAWN M. BOOTHE[1]

PHYSIOLOGY AND PATHOPHYSIOLOGY OF BEHAVIOR DISORDERS
DRUGS USED TO MODIFY BEHAVIOR
Antipsychotic Drugs
- **Structure-Activity Relationship**
- **Pharmacologic Effects**
- **Disposition**
- **Side Effects and Toxicity**
- **Drug Interactions**
- **Clinical Indications**

Antidepressant Drugs
- **Tricyclic Antidepressants**
- **Selective Serotonin-Reuptake Inhibitors**
- **Monoamine Oxidase Inhibitors**
- **Anxiolytics**
- **Anxioselective Drugs: Azapirones (Buspirone)**

Miscellaneous (Nonspecific) Drugs Used to Modify Behavior
- **Progestins**
- **Anticonvulsants**
- **Narcotic Agonists and Antagonists**
- **Antihistamines**
- **Beta Blockers**

Stimulants

PHYSIOLOGY AND PATHOPHYSIOLOGY OF BEHAVIOR DISORDERS

Little is known regarding the cellular mechanisms of abnormal behavior in humans or animals. The most likely neurotransmitters associated with abnormal behavior are assumed to be those targeted by drugs used to modify the behaviors. These include the biogenic amines, serotonin and histamine (H_1 subtype); the monoamine dopamine; the catecholamine norepinephrine; acetylcholine; γ-aminobutyric acid (GABA); and excitatory amino acids (Overall 1997; Simpson and Simpson 1996).

The drugs most effective in modifying behavior tend to be selective for serotonin (e.g., fluoxetine, clomipramine). Some studies support serotonin as the most likely neurotransmitter associated with abnormal behavior. For example, in cats, activation of serotonin receptor subtypes 5-HT$_{1A}$ and 5-HT$_{2/1C}$ in the hypothalamus modulates the expression of rage behavior (Shaikh et al. 1997). Serotonin is synthesized in the brain from tryptophan. Of at least nine serotonin (5-hydroxytryptamine, 5-HT) receptor subtypes found in the body, four appear to be particularly important (Simpson and Simpson 1996). Serotonin receptors differ in anatomical location and behavioral roles. The 5-HT$_1$ receptors, located primarily in the brain, are predominantly inhibitory (inhibition of adenyl cyclase), both pre- and postsynaptically. They appear to affect mood and behavior (Overall 1997). Regulation of serotonin action is complex, involving both pre- and postsynaptic mechanisms (Simpson and Simpson 1996).

Norepinephrine, the end product of dopamine oxidation, is inactivated primarily by active transport, i.e., reuptake from the synaptic-cleft presynaptic vesicles. It is deaminated by mitochondrial monoamine oxidases. Norepinephrine is located predominantly in the gray matter of the pons and in the medulla. Norepinephrine interacts with α_1 (via G-protein-mediated activation of phospholipase C and subsequent formation of inositol triphosphate) and β receptors (via activation of adenylyl cyclase) postsynaptically. Interaction with α_2 receptors (also via G proteins) occurs presynaptically. Norepinephrine appears to affect arousal, functional reward systems, and mood. The last effect may reflect a decrease in depression and an increase in mania.

Dopamine is synthesized from L-dopa in presynaptic vesicles; L-dopa is produced from dietary tyrosine (Simpson and Simpson 1996). Tyrosine is first oxidated (by tyrosine oxidase), then decarboxylated. Dopamine is metabolized by monamine oxidases (MAO) and catechol-*O*-methyltransferase (COMT). Dopamine receptors are distributed throughout the brain, but less so than norepinephrine. Dopamine appears to be largely located in the midbrain, hypothalamus, and limbic system (the part of the brain thought to control emotions) (Simpson and Simpson 1996). Dopamine receptors (at least five subtypes) also are found in portions of the extrapyramidal system responsible for coordinated movement (Overall 1997). At least four dopamine receptors are affected by mood disorders and stereotypies; increased dopamine appears to stimulate these abnormal behaviors (Overall 1997).

GABA is a major inhibitory neurotransmitter, being active at 30% of the synapses in the human central nervous system (CNS). It is formed from glutamate, which is widely distributed throughout the brain. Two primary receptor types, $GABA_A$ and $GABA_B$, appear to cause postsynaptic inhibition by facilitating chloride ion influx into the neuron. Several drugs, including benzodiazepines and barbiturates (such as phenobarbital), interact with the receptor in an agonistic fashion, causing neuronal inhibition (Overall 1997). The physiologic and behavioral effects of GABA and its receptors have not yet been well characterized (Simpson and Simpson 1996).

Excitatory neurotransmitters may increase and cause or be associated with several abnormal behaviors, including aggressive, impulsive, and schizophrenic disorders in humans. Among the more important excitatory neurotransmitters is glutamate. Glutamate is preformed and stored in synaptic vesicles that are released by calcium-mediated endocytosis. Barbiturates and progesterone modulate behavior, in part, by inhibiting calcium uptake and thus the release of glutamate at the neurotransmitter (Overall 1997).

Acetylcholine is the most widely distributed neurotransmitter in the brain (Simpson and Simpson 1996). It is produced from choline and rapidly metabolized by acetylcholinesterase. It tends to be an excitatory neurotransmitter. Like glutamate, it is preformed and stored at the terminal end of the synapse in vesicles that are stimulated by calcium to release the neurotransmitter by exocytosis. The primary significance of acetylcholine and behavior-modifying drugs is the likelihood of adverse reactions occurring when M_1 receptors are antagonized (Overall 1997).

Because neurotransmitters tend to be formed and degraded locally, both formation and inhibition offer pharmacologic targets. A number of drugs result in an increase in the presence of neurotransmitters in the synaptic cleft by inhibiting either the metabolism (e.g., dopamine) or the reuptake (e.g., serotonin, norepinephrine) of the neurotransmitter following release (Fig. 17.1).

DRUGS USED TO MODIFY BEHAVIOR

Drugs that modify behavior include the antipsychotic drugs (predominantly antidopaminergic in action), anxioselective drugs such as the azapirones (primarily antiserotonergic in action), drugs used to treat affective or mood disorders (antidepressants, lithium, and selected anticonvulsant drugs), and drugs used to treat anxiety and related disorders (anxiolytics, minor tranquilizers, benzodiazepines). Other drugs include antihistamines, beta blockers, progestins, anticonvulsants, and opioid antagonists. Many of these drugs are also used to treat other disorders and may be discussed elsewhere in this book. Only drugs that have veterinary application are discussed.

Care must be taken to distinguish behavior that is perceived to be abnormal by the pet owner from normal behavior. Pharmacologic management of abnormal behavior should be approached as an adjunct, and specifically as a facilitator, to normalizing behavior rather than as a cure. A number of nondrug techniques have been recommended by many animal behaviorists (Landsberg 1994; Voith 1985a,b, 1992; Houpt 1997a,b). Abnormal behaviors that require drug therapy should be simultaneously managed with behavioral modification training (e.g., decreasing arousal and fear can facilitate learning a new behavior; Juarbe-Diaz 1997a,b). The use of behavior-modifying drugs is not well studied in cats and dogs, and recommended indications are rarely based on well-controlled clinical trials. In addition, many of the drugs used to modify behavior can cause serious side effects, and the unpredictability of plasma or tissue drug concentrations increases the likelihood of adverse reactions. Many of the side effects may not be readily observed by the pet owner, further increasing the risk. Finally, slow response to therapy may lead to unsupervised manipulation of dosing regimens by the pet owner, again predisposing the animal to adverse reactions. Owners should be well counseled regarding the risks and benefits of behavior-modifying drugs, including potential changes in behavior that may be less desirable than the behavior targeted by the drug. Although many drugs recommended for use in dogs and cats are approved for human but not veterinary use, behavior-modifying drugs stand out as potential adverse risks (Johnson 1990). Obtaining informed owner consent is prudent prior to implementing therapy with these drugs. Caution should also be taken to prevent substance abuse by pet owners.

Monitoring serum drug concentrations may be of benefit for selected drugs. However, monitoring must be performed in conjunction with clinical response, including both efficacy and safety. Antidepressants should be used cautiously or not at all in patients suffering from metabolic illnesses. Adequate time must be given before a drug or a dosing regimen is considered to have failed. At least two drug elimination half-lives should elapse. In general, combinations of behavior-modifying drugs should be avoided. One drug should be withdrawn, often slowly, before another is begun. A drug-free period of two drug elimination half-lives is recommended in humans before a new drug is begun. Generally, 10–20 days should elapse for a short-acting drug and up to 6–8 weeks for longer acting drugs (Overall 1997).

The descriptions of drug therapy for selected behaviors that follow (see also Table 17.1) are not intended to be used as a "cookbook" approach to managing abnormal behavior in dogs and cats. Rather, clinicians should familiarize themselves with the assumed behavior and its proper nondrug behavioral modification management. Clinicians should be thoroughly familiar with the drug to be used. Because indications are less clear with these drugs, emphasis should be placed on side effects, drug interactions, and contraindications. Consultation with a veterinary animal behaviorist is strongly recommended prior to implementing any drug therapy.

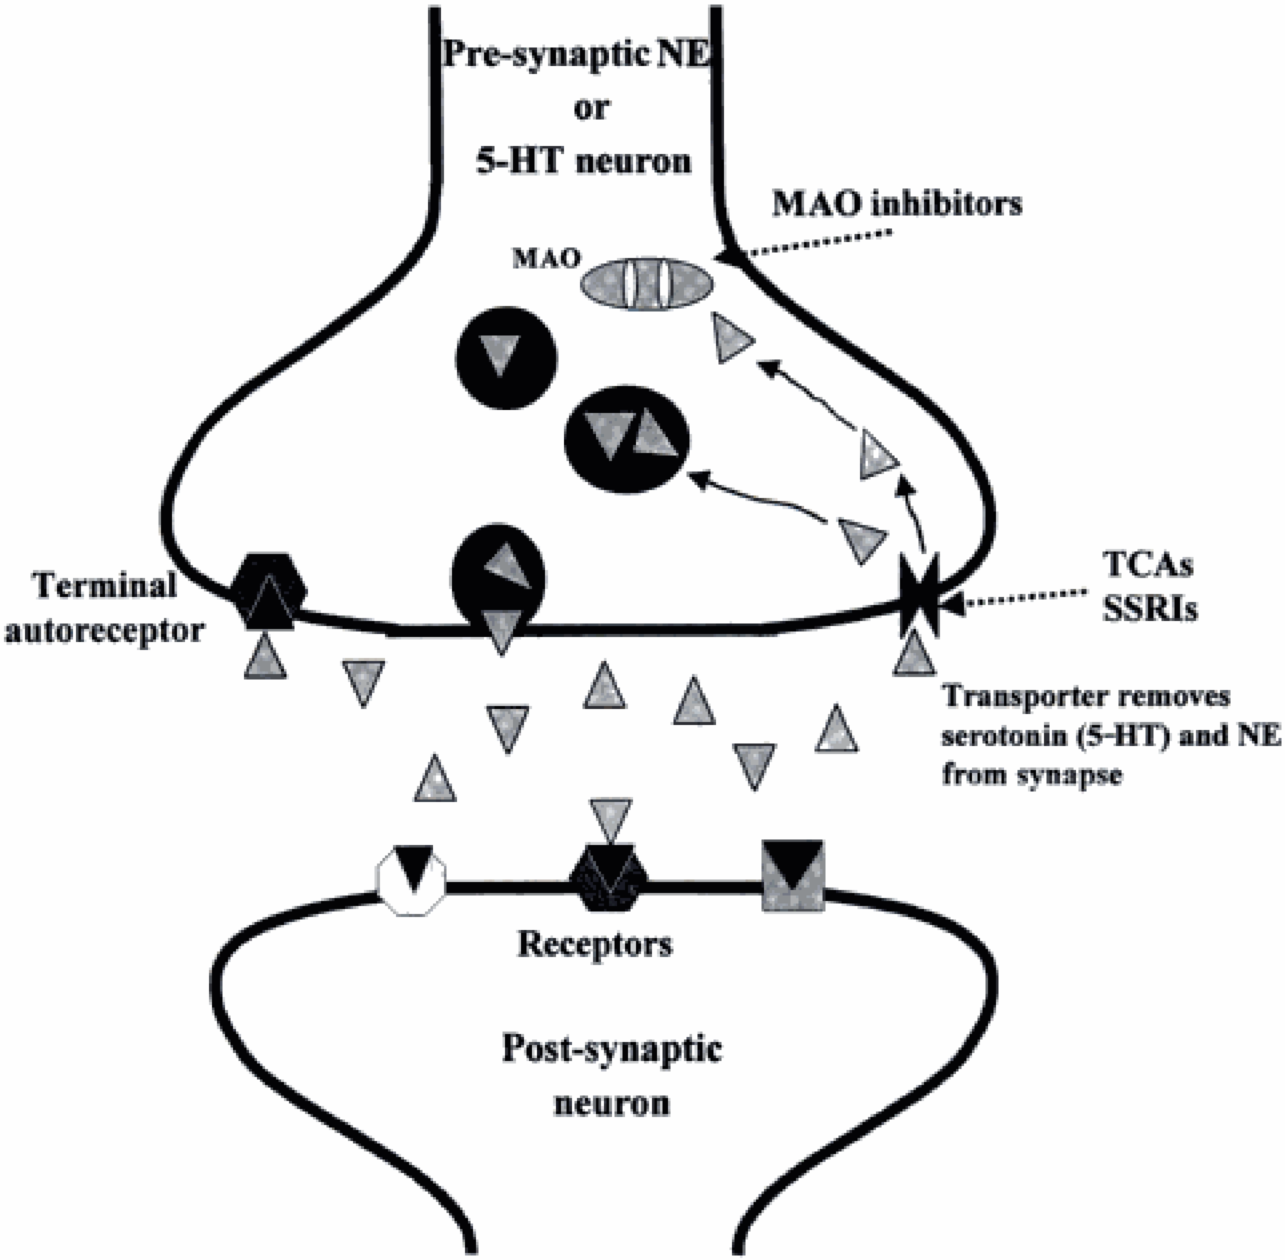

FIG. 17.1—Mechanism of action of selected behavior-modifying drugs. Neurotransmitters responsible for behavior are released from the presynaptic neuron into the synaptic cleft and interact with postsynaptic receptors. Following exocytosis, inactivation of the transmitter occurs primarily by reuptake into the presynaptic neuron, the site of action of most behavior-modifying drugs (TCAs = tricyclic antidepressants; SSRIs = selective serotonin reuptake inhibitors; NE = norepinephrine). Activation also may involve metabolic degradation, as in the case of the monamine oxidases (MAO).(Reprinted, with permission, from Boothe in press.)

ANTIPSYCHOTIC DRUGS. Psychotic disorders in humans involve a severe disturbance of brain function characterized by thought and speech disruption and hallucinations or delusions (Simpson and Simpson 1996). Although psychotic disorders do not occur in veterinary medicine, drugs developed for their management in humans have proven efficacious for a number of veterinary applications. Antipsychotic drugs (also called neuroleptics or major tranquilizers) include the phenothiazines, thioxanthenes (structurally related to the phenothiazines), heterocyclic dibenzepines, butyrophenones, and diphenylbutylpiperidines (Baldessarini 1996a) (Fig. 17.2).

Structure-Activity Relationship. Antipsychotic drugs are categorized by structure and by potency. Low-potency drugs (chlorpromazine, acepromazine, promazine) are characterized by greater sedation and more cardiac and anticholinergic side effects than their high-potency counterparts. High-potency drugs (e.g., haloperidol, fluphenazine, trifluoperazine, prochlorperazine, and thiothixene) are administered at lower doses

TABLE 17.1—Doses of drugs used to modify behavior in small animals

Drug	Class	Dose	Route	Interval (hr)
Acepromazine	Phenothiazine	1–2 mg/kg	PO	8
	Sedative	0.05–0.1 mg/kg	IV, IM	8
Alprazolam	Benzodiazepine	0.01–0.1 mg/kg [D] (not to exceed 4 mg)	PO	As needed
	Anxiolytic	0.125–0.25 mg/kg [C]	PO	12
Amitriptyline	TCA	1–4.4 mg/kg [D]	PO	12–24
		0.5–2.0 mg/kg [C]	PO	12–24
Buspirone	Azaperone	2.5–10 mg [D] (not to exceed 2 mg/kg)	PO	24
	Anxioselective	1 mg/kg [D]	PO	8–12
		0.5–1 mg/kg [C]	PO	8–12
Carbamazepine	Anticonvulsant	400–1600 mg	PO	Divided every 8–12 hr
		4–8 mg/kg [D]	PO	8-12
Clomipramine	TCA	1–3 mg/kg [D] (not to exceed 200 mg/day)	PO	12–24, increasing dose at 14-d intervals
		0.5 mg/kg [C]	PO	24
Clonazepam	Benzodiazepine	1–10 mg [D]	PO	6–24
	Anxiolytic	0.5–1.5 mg/kg [D]	PO	
Clorazepate	Benzodiazepine Anxiolytic	0.5–1 mg/kg	PO	12–24
	Benzodiazepine sustained delivery Anxiolytic	11.25--22.5 mg/dog	PO	12–24
Dextrometamphetamine	Stimulant	2.5–5 mg (medium-sized dog)	PO	12-24
Diazepam	Benzodiazepine Anxiolytic	0.25–1 mg/kg	PO	6–12
	Benzodiazepine sustained delivery Anxiolytic	0.5–1 mg/kg	PO	12–24
Doxepin	TCA (antihistaminergic)	3–5 mg/kg [D]	PO	12
Fluoxetine	SSRI	1 mg/kg [D]	PO	12–24
	Antidepressant	0.5–1 mg/kg [C]	PO	24
Haloperidol	Tranquilizer Butyrophenone	1–4 mg [D]	PO	12
Hydrocodone	Opioid agonist	0.25 mg/kg [D]	PO	8
		0.25–1 mg/kg [C]	PO	8–12
Hydroxyzine	Antihistamine (H_1)	2.2 mg/kg	PO	8
Imipramine	TCA	2.2–4.4 mg/kg [D]	PO	12–24
Lorazepam	Benzodiazepine Anxiolytic			
Medroxyprogesterone acetate	Progestin	11 mg/kg	IM, SC	As needed (3–6 mo)
Megestrol acetate	Progestin	1–2 mg/kg (up to 4 mg/kg; see text)	PO	24 for 7–14 d then decreasing doses by ½ until discontinued at 3–6 wk
Methylphenidate	Stimulant	0.25 mg/kg [D]	PO	12–24?
Nalfeme	Opioid antagonist	1–4 mg/kg	IM	As needed
Naloxone	Opioid antagonist	11–22 μg/kg	IV, SC, IM	As needed
Naltrexone	Opioid antagonist	1–4 mg/kg	PO	12–24
Nortryptiline	TCA (metabolite of amitriptyline)	1–2 mg/kg [D]	PO	12
Oxazepam	Anxiolytic Benzodiazepine	0.2–0.5 mg/kg [C]	PO	12–24
Paroxetine	SSRI	1 mg/kg	PO	24
Perphenazine	Phenothiazine Tranquilizer	0.88 mg/kg	PO	8–12
Pindolol	Beta blocker	0.124–0.25	PO 24	
Propranolol	Beta blocker	0.5–2 mg/kg	PO	8
Protriptyline	TCA	5 mg [D]	PO	24, at bedtime
Thioridazine	Phenothiazine	1.1–2.2 mg/kg [D]	PO	12–24

Note: [D] = dog; [C] = cat; TCA = tricyclic antidepressant; SSRI = selective serotonin-reuptake inhibitor.

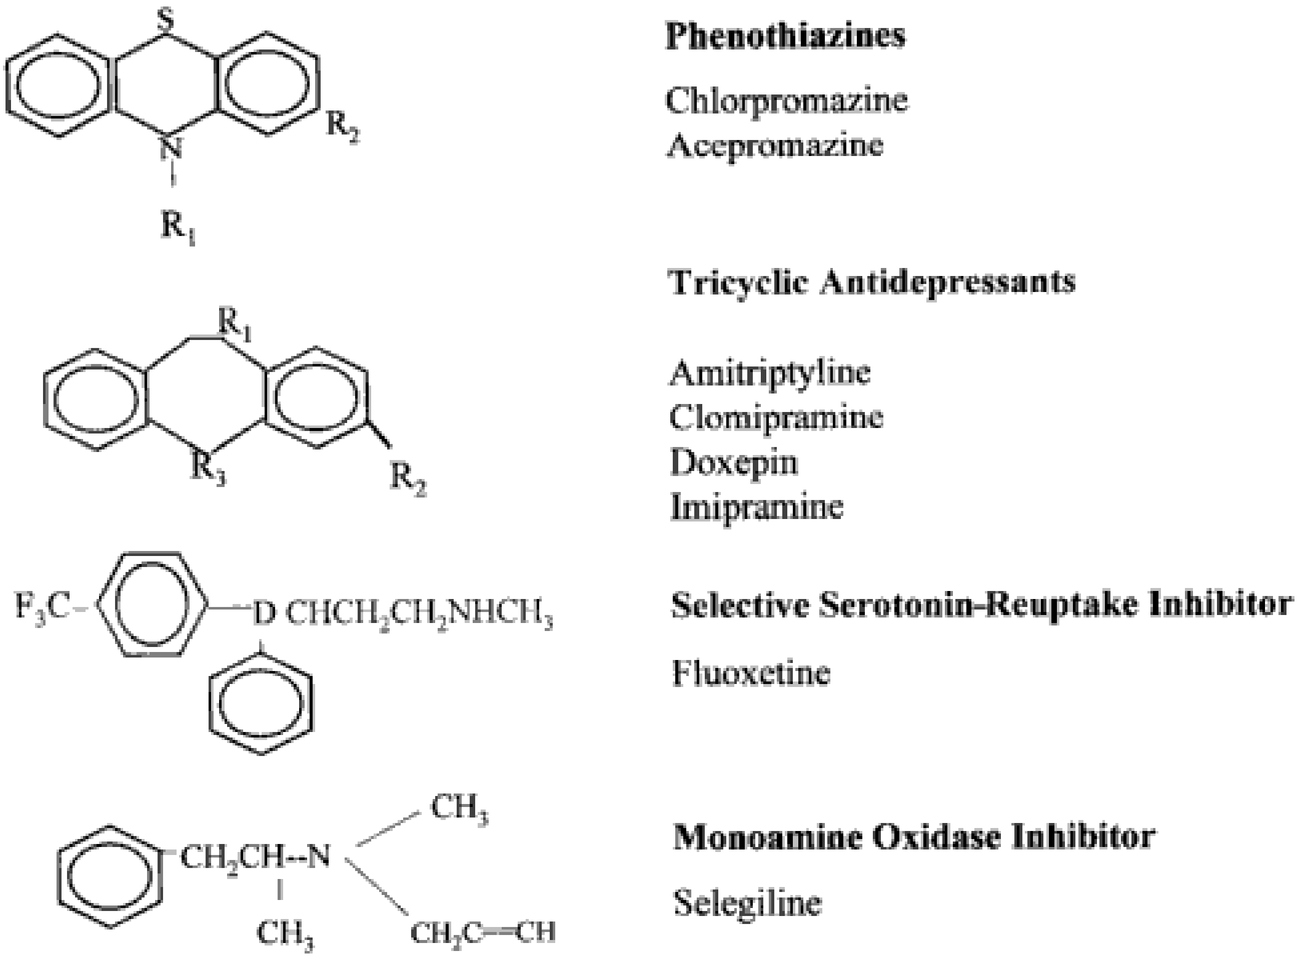

FIG. 17.2—Structures of selected behavior-modifying drugs. (Reprinted, with permission, from Boothe in press.

and are associated with less sedation and fewer anticholinergic and cardiac side effects. However, they have a greater incidence of extrapyramidal side effects. The largest structural class of antipsychotics is composed of the phenothiazines, or tricyclic antipsychotics (not to be confused with the tricyclic antidepressant drugs) (Baldessarini 1996a).

Tricyclic antipsychotic drugs are represented by phenothiazine, a three-ring structure containing a sulfur and a nitro group in the ring connecting two benzene rings. Substitutions on one of the benzene rings yield different drugs (e.g., chlorpromazine, promazine), which differ in efficacy (Fig. 17.2). The pharmacology is also impacted by substitutions on the nitro groups such that potency (but not efficacy) is reduced by an aliphatic side chain (e.g., chlorpromazine, thorazine, acepromazine, and trifluopromazine) (Baldessarini 1996a). The length of the side chain also determines antihistaminergic properties, with two-carbon side chains such as that occurring in promethazine being more antihistaminergic. Drugs with higher potency have a piperazine side chain, including fluphenazine and rifluoperazone. Esterification with long-chain fatty acids results in long-acting (due to slow hydrolysis and absorption) drugs (e.g., fluphenazine enanthate and decanoate) (Baldessarini 1996a). The use of these long-acting drugs in veterinary medicine has yet to be established.

The butyrophenone antipsychotics include haloperidol (the prototype) and droperidol. The latter is very short acting and highly sedative; thus its use is limited to anesthetic regimens (Baldessarini 1996a).

Pharmacologic Effects. The pharmacologic effects of antipsychotic drugs generally are similar in human beings and animals (Baldessarini 1996a). Phenothiazines are also categorized as tranquilizers. As tranquilizers, the phenothiazines are calming in nature, causing a decrease in spontaneous activity and generally a decrease in response to external stimuli (Overall 1997). The predominant antipsychotic action of the phenothiazines is neuroleptic, a term derived from the effect of the drugs on human psychiatric patients and intended to indicate the difference from signs typical of CNS depression (Baldessarini 1996a). The neuroleptic effects are attributed (but not conclusively) to antidopaminergic effects at D_2 dopamine receptors (Baldessarini 1996a). Some of the neuroleptics (e.g., phenothiazines) have high affinity for and thus also antagonize D_1 receptors, although pharmacologic effects at these receptors appear to be minimal. Phenothiazines also block D_3 and D_4 (which are D_2-like) receptors. Selected "atypical" antipsychotic drugs (e.g., clozapine) have a low affinity for D_2 receptors and are not characterized by extrapyramidal effects. However, they are characterized by α_1-adrenergic antagonism. Some of the antipsychotic drugs also have affinity for serotonergic (5-HT_2) receptors (e.g., clonazpine). Cholinergic and histaminergic (H_1) receptors also are targeted by some of the drugs, resulting in unique pharmacologic effects among the neuroleptics. Variable interactions with different receptor types lead to unpredictable effects on the autonomic nervous system (ANS). Among the neuroleptics, chlorpromazine has significant α-adrenergic antagonistic actions. In general, the antimuscarinic actions of neuroleptics are weak.

Neuroleptic effects include suppression of spontaneous movements or complex behaviors but minimal effects on spinal reflexes and unconditioned nociceptive avoidance behaviors. Interest in the environment is minimized as are manifestations of emotion. Patients are easily aroused; ataxia or incoordination should not be evident at appropriate doses (Baldessarini 1996a). Aggressive or impulsive behavior should gradually diminish. As a result, conditioned avoidance (but not unconditioned escape or avoidance) behavior and exploratory behavior are minimized. Feeding and emesis also are inhibited. At high doses, cataleptic immobility is evident (particularly in cats; Simpson and Simpson 1996), resulting in increased muscle tone (and the ability to place animals in an abnormal posture) and ptosis. Akathisia, an increase in restless activity, is an undesirable side effect that occurs in human beings but apparently not in animals. Akathisia occurs as adaptive responses to phenothiazines increase in extrapyramidal tissues (Baldessarini 1996a).

The effects of phenothiazines occur throughout the CNS. Cortical effects are responsible for many of the neuroleptic actions. Many of these sites appear to be spared from the adaptive changes of tolerance (Baldessarini 1996a). Neuroleptics have been associated with an increased incidence of seizures. Many of these drugs lower seizure threshold as well as induce discharges typical of epileptic seizures. Aliphatic, low-potency phenothiazines are particularly characterized by this effect (Baldessarini 1996a). Although the effect is more likely to occur in patients who are epileptic or are predisposed to seizures, the effect is also characterized by dose dependency in some drugs. Thus, these drugs should not be used in epileptic patients or patients undergoing withdrawal from central depressants (Baldessarini 1996a). Increasing doses slowly and accompanying anticonvulsant therapy are indicated if the drugs must be used in epileptic patients. Antagonism of D_2 receptors is largely responsible for the various extrapyramidal effects of the drugs.

The neuroleptic drugs have a number of effects in the limbic system. Although D_2 antagonism occurs in the limbic system, attempts are being made to identify D_3-selective drugs for treatment of psychoses because D_3 receptor stimulation may be responsible for many of the behaviors targeted by neuroleptics (Baldessarini 1996a). Neuroleptics stimulate prolactin secretion in human beings. Indeed, the potency of neuroleptic action and ability to cause prolactin secretion are well correlated for most drugs. Tolerance to this effect is not likely to develop. In humans, prolactin secretion caused by neuroleptics is also responsible for breast engorgement and galactorrhea. Releases of growth hormone and corticotropin-releasing hormone (especially chlorpromazine) occur in response to stress; neuroleptics also interfere with the release of growth hormone, although apparently not sufficient for treatment of acromegaly. Impaired release of serotonin may result in weight gain (particularly low-potency drugs), and glucose tolerance and insulin release may be impaired in prediabetic patients (especially chlorpromazine) (Baldessarini 1996a).

In the brain stem, the neuroleptics have little effect, even in cases of acute overdosing. Life-threatening coma is rare. In contrast, most neuroleptics protect against nausea and emesis at the chemoreceptor trigger zone in the medulla. These effects occur at low doses. Potent piperazines and butyrophenones are also often effective against nausea stimulated by the vestibular system (Baldessarini 1996a).

Phenothiazines characterized by lower potency have a predominant sedative effect that is more apparent initially but tends to decline as tolerance develops. The phenothiazines are characterized by anxiolytic effects, but more specific anxiolytic drugs are available. In addition, the risk of either autonomic (e.g., low-potency drugs) or extrapyramidal effects (e.g., highly potent drugs) increases the likelihood of causing anxiety (Baldessarini 1996a).

The neuroleptic drugs impart physiologic (especially cardiovascular) effects due to peripheral actions. However, the effects are complex because the neuroleptics interact with a number of receptor types that have cardiovascular effects. Hypotension induced by phenothiazines (low potency in particular) reflects direct effects on the blood vessels, indirect actions in the CNS and autonomic receptors, and a direct negative inotropic effect on the heart. Chlorpromazine has antiarrhythmic effects on the heart, similar to quinidine.

Disposition. The antipsychotics are characterized by variable bioavailability, high lipophilicity, high protein binding, and accumulation in a number of tissues. Elimination occurs primarily through hepatic metabolism. In humans, the elimination half-life is long, ranging from 20 to 40 hours. Biologic effects persist for longer than 24 hours, allowing once-daily therapy in people (Baldessarini 1996a). Metabolites can be detected in urine for several months.

Side Effects and Toxicity. Despite the variety of potential side effects, the antipsychotic drugs tend to be very safe. Lethal ingestion is rare in human patients.

Side effects tend to reflect the pharmacologic actions of the drugs and include CNS, cardiovascular, endocrine, and autonomic effects (Baldessarini 1996a). In human patients, other effects include dry mouth, blurry vision, and constipation. Urinary retention may occur in male patients with prostatitis. Extrapyramidal neurologic side effects occur in people but have not been reported in animals. However, some animals have exhibited signs of hyperactivity after treatment with acepromazine (Simpson and Simpson 1996). In addition, at least one report cites increased agitation and irritability following treatment of aggression with acepromazine (Marder 1991). Jaundice has occurred in people following administration of chlorpromazine and may resolve with continued treatment. Blood dyscrasias, including leukopenia, eosinophilia, and leukocytosis, occur but are less common with low-potency phenothiazines. Skin reactions tend to be common in people, again more often with low-potency phenothiazines.

Drug Interactions. Chlorpromazine is used in combination anesthetic regimens because of its ability to potentiate central depressants. Effects of analgesics and sedatives also can be enhanced. Interactions with antihypertensive drugs can be unpredictable and are more likely to be adverse with low-potency products (Baldessarini 1996a). Selected phenothiazines can antagonize the positive inotropic effects of digoxin.

Clinical Indications. In general, the use of phenothiazines for treatment of aggressive behavioral abnormalities is inappropriate because they blunt normal, as well as abnormal, behavior. Acepromazine is particularly problematic. Restraint of aggressive dogs with the drug renders dogs more likely to be reactive to noises and more easily startled (Overall 1997). In addition, because the degree and duration of tranquilization vary, reactions in dogs are unpredictable. Phenothiazines are not selective as antianxiety drugs but can reduce responsiveness in general and thus be useful in some cases of episodic anxiety (Simpson and Simpson 1996). Thioridazine has been used in one case of aberrant motor behavior (Jones 1987).

ANTIDEPRESSANT DRUGS. Much of the information regarding the use of mood-modifying drugs in animals has been extrapolated from human use. These drugs are characterized by clinical pharmacology and mechanisms of action that are likely to markedly differ among animals. Nevertheless, little scientific information is available to guide their use in animals. Currently, none of these drugs are approved for use in animals.

In people, affective (behavior) disorders targeted by tricyclic antidepressants range from depression to manic-depressive disorders. In animals, the list of targeted disorders is much greater and often appears to include any type of behavior deemed "unacceptable" by pet owners. Among the human drugs that have been used in animals are the tricyclic antidepressants, the MAO inhibitors (selegiline), and selective serotonin-reuptake inhibitors (SSRIs, fluoxetine). To best understand the pharmacologic actions (intended and undesirable) of these drugs, it is necessary to appreciate the extent to which neurotransmitters targeted by these drugs are active in the brain. Among the most commonly targeted neurotransmitters is the biogenic amine system, with norepinephrine, 5-hydroxytryptamine (5-HT, serotonin), and dopamine serving as primary targets. However, acetylcholine and histamine are common, although generally secondary, targets. In addition, α-adrenergic receptors may be stimulated by some of these drugs. The pharmacologic effects (and side effects) of these drugs vary with the neurotransmitter targeted. Drugs that are more specific in their actions tend to be safer. The inability to predict the effect of antidepressant drugs on behavior reflects, in part, the inability to predict effects at the synapse, as well as a lack of knowledge regarding the impact of neurotransmission on behavior. In general, blockade of dopamine transport appears to be stimulatory rather than antidepressant. Inhibition of serotonin reuptake appears to be antidepressant. Inhibition of norepinephrine reuptake consistently yields antidepressant actions.

Tricyclic Antidepressants

Structure-Activity Relationship. The tricyclic antidepressants (TCA) are among the most frequently prescribed drugs in human behavior medicine. Their name reflects their chemical structure (Fig. 17.2). The TCAs were identified as a group of potentially useful drugs for the modification of behavior in the 1940s following the generation of a number of drugs with antihistaminergic, sedative, analgesic, and antiparkinsonian effects. Imipramine was selected based on its hypnotic and sedative effects. Imipramine differs from phenothiazines only by the replacement of sulfur with an ethylene bridge, yielding a seven-member ring. This compound proved ineffective in quieting agitated psychotic patients but was very effective for selected mood disorders (Baldessarini 1996b). The search for chemically related compounds yielded a number of additional drugs. Clomipramine, amitriptyline, and doxepin are all derivatives of imipramine (Baldessarini 1996b). Each contains a tertiary amine at one of the substitution sites on the seven-member ring. Desipramine, a major metabolite of imipramine, and nortriptyline, the *N*-demethylated metabolite of amitriptyline, are secondary amine tricyclics. Proptriptylline and trimipramine are other TCAs but have few veterinary applications (Simpson and Simpson 1996; Shores and Redding 1987). The effects of neurotransmitter reuptake vary with the different amine structures (Baldessarini 1996b).

Mechanism of Action. The mechanism of action of the TCAs (and of the MAO inhibitors and the SSRIs) is blockade of the mechanisms of physiologic inactivation. For the TCAs, the mechanism is inhibition of reuptake at presynaptic biogenic amine neurotransmitter receptors in the brain. As reuptake is inhibited, the concentration of neurotransmitters increases, prolonging their actions (CNS stimulation). The chemical structure of the TCAs determines, in part, which neurotransmitters are affected (Baldessarini 1996b). Imipramine and its derivatives with a tertiary-amine side chain block norepinephrine reuptake but have little effect on dopamine reuptake. The secondary amine derivatives of imipramine are potent and highly selective inhibitors of norepinephrine reuptake; however, they are characterized by fewer autonomic and anticholinergic effects. Tertiary amines that are metabolized in the patient to secondary amines will exhibit the effects on norepinephrine reuptake. Clomipramine has marked effects on serotonin reuptake. Doxepin is characterized by greater antihistaminergic actions (thus explaining its frequent recommendation for chronic pruritus). Although amitriptyline has been the most commonly prescribed drug in animals, clomipramine has recently been approved for use in dogs and may be more appropriate for clinical studies because of its relative selectivity for serotonin.

PHARMACOLOGIC EFFECTS

ADAPTATION TO PHARMACOLOGIC EFFECTS. The effect of TCAs at pre- and postsynaptic receptors and autoregulation result in complex responses that are not well understood. Although inhibition of reuptake occurs very rapidly, peak effects still take several weeks. This prolonged time to maximal effect reflects in part disposition (see section on clinical pharmacology) but also appears to reflect adaptation in the CNS to changes in neurotransmitter concentrations at the synapse. Administration of a TCA results in an immediate decrease in the synthesis and release of norepinephrine or serotonin (depending on the major target of the TCA) in selected areas of the brain. The effects appear to be mediated presynaptically through autoreceptors (α_2 or serotonin, respectively). However, turnover gradually normalizes within 1–3 weeks. Autoreceptors appear to be down-regulated and become desensitized to the presence of the TCA (Baldessarini 1996b). The number and sensitivity of postsynaptic adrenergic receptors do not appear to be impacted by continued use of TCAs.

Adaptive responses appear to influence the pharmacologic properties of TCAs at adrenergic receptor sites. The TCAs have a moderate affinity for α_1 receptors and only limited affinity for α_2 and β receptors. Changes in serotonin receptors following repeated treatment with TCAs are complex. Although the impact is not clear, the general effect appears to be increased sensitivity to serotonin. This may be an important component in the outcome of prolonged treatment (Baldessarini 1996b). The TCAs also appear to impact the effect of other neurotransmitters and their receptors, including GABA (unknown significance) and dopamine (D_2; desensitization of autoreceptors, resulting in mood elevation). Other factors to consider regarding adaptation to TCA effects include changes in cyclic-AMP-dependent protein kinases and potential changes at the level of gene expression (Baldessarini 1996b).

In addition to tolerance (to sedative and autonomic effects), physical dependence can develop to the TCA. Physical dependence following acute withdrawal is manifested in human patients as malaise, chills, coryza, and muscle aches (Baldessarini 1996b). Slow discontinuation of the drug is recommended.

AUTONOMIC NERVOUS SYSTEM. The predominant effect of TCAs on the ANS appears to reflect inhibition of norepinephrine transport into adrenergic nerve terminals and antagonism of muscarinic, cholinergic, and α_1-adrenergic responses to the neurotransmitters. Blurred vision, dry mouth, constipation, and urinary retention at therapeutic doses (documented in humans) appear to reflect anticholinergic effects (Baldessarini 1996b).

CARDIOVASCULAR SYSTEM. Cardiovascular effects of TCAs occur at therapeutic doses and can become life-threatening with overdosing. Postural hypotension occurs in human beings due to α-adrenergic blockade. Mild sinus tachycardia occurs due to inhibition of norepinephrine uptake and muscarinic (M_1) blockade (Baldessarini 1996b). Conduction time is prolonged, especially at concentrations above 200 ng/mL. The TCA also can directly suppress the myocardium (Baldessarini 1996b). The myocardial depressant effects are greater in the presence of underlying cardiac disease.

CLINICAL PHARMACOLOGY. The disposition of the TCA favors adverse reactions in that the characteristics of disposition tend to vary greatly among animals and extrapolation between species is complicated. Unfortunately, the disposition of the drugs has not been scientifically studied in animals and information is extrapolated from human beings. The TCAs are very lipophilic. As such, they are well absorbed following oral administration. However, they can undergo marked first-pass metabolism. High doses can cause anticholinergic effects on the gastrointestinal tract, slowing absorption or making it erratic. Absorption in humans can result in peak concentrations as rapidly as 2 hours or as long as 12 hours after administration (Baldessarini 1996b). The drugs are very highly protein bound, but unbound drug is characterized by a very large volume of distribution (10–15 L/kg in human patients), contributing to a long elimination half-life. Drug may bind avidly to selected tissues. Drugs are eliminated by hepatic (oxidative) metabolism. Metabolism is variable among human patients, accounting for plasma concentrations that differ by 10- to 30-fold. Metabolism yields active and inactive metabolites. It is not clear what percentage of the antidepressant activity of the TCA is associated with the metabolites. Metabolites generally have an elimination half-life that is at least twice that of the parent compound (Baldessarini 1996b). Thus, accumulation of the metabolites can result in a marked proportion of the pharmacologic effect of TCAs.

SIDE EFFECTS. Up to 5% of human patients receiving a TCA react adversely. Sedation is common (Simpson and Simpson 1996), although clomipramine generally is associated with less sedation than the other TCAs (Juarbe-Diaz 1997a). The most common reactions are due to the antimuscarinic effect or overdosing. Cardiac toxicity is a less frequently reported but serious toxicity. Side effects include dry mouth, gastric distress, constipation, dizziness, tachycardia or other arrhythmias, blurred vision, and urinary retention (particularly problematic in the presence of prostatitis hypertrophy) (Baldessarini 1996b). Weakness and fatigue reflect CNS effects. Cardiac toxicity is more likely in patients that start therapy with cardiac disease. In healthy patients, the most likely cardiac response is hypotension due to α-adrenergic blockade.

An undesirable side effect of antidepressant drugs in people is referred to as the "switch process." Patients undergo a transition from depression to hypomanic or manic excitement (Baldessarini 1996b). This effect has not been reported in animals. Confusion and delirium are behavior aberrations that occur commonly in human patients, with the incidence of 10% in all patients increasing to greater than 30% in patients over 50 (Baldessarini 1996b). Miscellaneous toxic effects in human patients include leukopenia, jaundice, and skin rashes. Weight gain occurs, particularly with the drugs that are selective for serotonin reuptake. Reports addressing the side effects of TCAs in dogs are uncommon. Goldberger and Rapoport (1991) reported side effects in 5 of 13 dogs receiving clomipramine for lick granuloma. Clinical signs included lethargy, anorexia, diarrhea, and growling.

Acute poisoning with TCAs is common in human patients (accidental or intentional) and appears to be a significant problem in animals (Johnson 1990). Symptoms in humans vary and are complex. Excitement and restlessness may be accompanied by myoclonus or tonic-clonic seizures. Coma may rapidly develop, associated with depressed expiration, hypoxia, hypothermia, and hypotension (Baldessarini 1996b). Anticholinergic effects include mydriasis, dry mucosa, absent bowel sounds, urinary retention, and cardiac arrhythmias, including tachycardia. Clinical signs reported following accidental ingestion in animals (Johnson 1990) include hyperexcitement and vomiting as early manifestations, followed by ataxia, lethargy, and muscular tremors. Bradycardia and other cardiac arrhythmias occur later. These later signs occurred shortly before death in experimental animal models of TCA toxicoses (Johnson 1990).

Treatment for TCA toxicoses is supportive, including respiratory (intubation) and cardiovascular support. Gastric lavage with activated charcoal can be used early. Emetics probably should be avoided because of the risk of aspiration pneumonia in seizuring animals (emetics may further predispose the animal to seizures). Short-acting barbiturates (or similar drugs) without preatropinization are preferred for anesthetic control during gastric lavage. Cathartics (sorbitol or sodium sulfate–Glauber's salt) can be of benefit. Magnesium sulfate should not be used because impaired gastrointestinal motility can facilitate absorption of magnesium. Resolution of coma may require several days; the threat of cardiac arrhythmias likewise persists for several days. Pharmacologic interventions for cardiac arrhythmias have not been well established. Alkalinization (sodium bicarbonate sufficient to maintain blood pH above 7.5: 2–3 mEq/kg over 15–30 minutes IV) may prevent death by increasing protein binding and cardiac automaticity (due to potassium shifts) (Johnson 1990). Cardiac drugs, including antiarrhythmics and digoxin, are contraindicated in human patients. Phenytoin may provide antiarrhythmic effects and in human patients is useful for treatment of seizures (Baldessarini 1996b). This latter effect is not likely to occur safely in animals. Diazepam is indicated for acute management of seizures. Beta-adrenergic receptor antagonists and lidocaine may be useful (Baldessarini 1996b). The risk of tonic-clonic seizures increased in human patients, particularly at high doses.

CLINICAL INDICATIONS. The TCAs have been recommended by animal behaviorists for most abnormal behaviors manifested in dogs and cats. These include, but are not limited to, behaviors associated with fear and aggression (Juarbe-Diaz 1997a,b; Overall 1997; Haupt 1997; Marder 1991), stereotypies, obsessive-compulsive or self-mutilation disorders, and excessive barking. Clomipramine recently has been approved for use in dogs (ClomCalm®, Novartis Animal Health) for treatment of separation anxiety. Protriptyline is a nonsedative TCA that has been used successfully in human narcoleptic patients. The drug has been used successfully in one dog whose narcolepsy was manifested as hyperinsomnia (Shores and Redding 1987).

CONTRAINDICATIONS. The TCAs should be avoided in animals with metabolic diseases. Specific contraindications include a history of cardiac or hepatic disease, seizures, glaucoma, hyperthyroidism, or thyroid hormone supplementation (Juarbe-Diaz 1997a).

DRUG INTERACTIONS. The TCAs can interact with a number of other drugs. Competition for protein-binding sites with other highly protein-bound drugs can result in increased drug concentrations. Drugs that impact drug-metabolizing enzymes, through either inhibition or induction, will impact the clearance of TCAs. The sequelae of the impact are difficult to predict since active metabolites similarly will be impacted. However, in general, drugs that inhibit metabolism are likely to result in greater drug accumulation and increased risk of toxicity. Other antidepressants and TCAs can also compete with other compounds for metabolism. The drugs themselves may impact metabolism of other drugs. Clomipramine inhibits the metabolism of other drugs (Baldessarini 1996b). Antidepressants potentiate the effects of sedative drugs. In general, TCAs should not be used in combination with other drugs that modify CNS neurotransmitters, such as MAO inhibitors and amitraz (Juarbe-Diaz 1997a). In human patients, a potentially lethal interaction has been reported when a TCA, particularly one that inhibits serotonin uptake, is combined with a MAO (Baldessarini 1996b). The term "serotonin syndrome" has been applied to the interaction, which is characterized by restlessness, muscle twitches, hyperreflexia, shivering, tremors, etc.

CLINICAL USE. Most antidepressant drugs require 2–3 weeks for clinical efficacy to be realized. The exception might be amitriptyline, which may cause response within 3–5 days (Juarbe-Diaz 1997a). Therapeutic drug monitoring may facilitate the safe and effective use of the drugs. In human patients, plasma concentrations that range from 100 to 250 ng/mL are most likely to cause satisfactory antidepressant effects; toxicity can be expected at concentrations above 500 ng/mL, with fatal consequences likely as concentrations approach 1000 ng/mL (Baldessarini 1996b). Variability among human patients (and presumably among animals) supports the use of monitoring to guide therapy. However, monitoring to avoid toxicity is complicated because serum concentrations by themselves are not reliable predictors of toxic responses.

Because of the risk of withdrawal due to physical dependence, discontinuation of TCAs should occur over a week or longer if therapy has been prolonged (Baldessarini 1996b).

Selective Serotonin-Reuptake Inhibitors

STRUCTURE-ACTIVITY RELATIONSHIP AND MECHANISM OF ACTION. The SSRIs enhance CNS serotonin by blocking presynaptic neuronal uptake. They may also increase postsynaptic receptor sensitivity (Simpson and Simpson 1996). Drugs currently approved in humans include fluoxetine, paroxetine, sertraline, and fluvoxamine. Because of their selectivity for serotonin uptake, the diverse effects characterizing TCAs are generally absent with SSRIs.

CLINICAL PHARMACOLOGY. The clinical pharmacology of the SSRIs is similar to that of the TCAs. Oral absorption, lipophilicity, protein-binding, and volume of distribution are similar. Like the TCAs, fluoxetine is metabolized by the liver to active (norfluoxetine) and inactive metabolites (Baldessarini 1996b). The active metabolite is very long acting. In addition, it interferes with the metabolism of other antidepressants (including the TCAs), prolonging metabolite elimination even when the parent drug is no longer present. The elimination half-life of norfluoxetine is 150–200 hours in people, compared to 50 hours for the parent compound. Thus, based on accumulation alone, the metabolite can have a profound impact on therapeutic effect. Paroxetine and fluvoxamine have no active metabolites (in human patients). The time to efficacy of SSRIs (which is up to 3 weeks in human patients) reflects, in part, the time for maximum accumulation of the parent drug and its metabolites.

The use of monitoring to guide therapy was addressed with the TCAs. As with the TCAs, effective concentrations have not been established in animals but must be extrapolated from people. The relationship between plasma drug concentrations and therapeutic efficacy has not been well established (Simpson and Simpson 1996). Plasma concentrations thought to be effective in human patients range from 100 to 300 ng/mL for fluoxetine (and its active metabolites). Effective concentrations for paroxetine are 30–100 ng/mL; for sertraline, 25–50 ng/mL (Baldessarini 1996b).

DRUG INTERACTIONS. The SSRIs can inhibit the metabolism of other drugs; the order of potency of inhibition is paroxetine > norlouoxetine > fluoxetine = sertraline. Because of the risk of drug interactions, SSRIs should not be used in combination with other antidepressants (see discussions on serotonin syndrome and on drug interactions of TCAs and MAO inhibitors) (Baldessarini 1996b).

SIDE EFFECTS. Compared to the TCAs, SSRIs appear to be safe. Unlike the TCAs, SSRIs have minimal effects on the cardiovascular system (Baldessarini 1996b). However, the safety of their use in patients with underlying cardiac disease has not been established. Sedation is not a common side effect, being least likely with fluoxetine (Simpson and Simpson 1996). In humans, gastrointestinal side effects are the most common, occurring in as many as 25% of patients receiving the drug (Simpson and Simpson 1996). Their incidence is minimized by starting with a low dose and gradually increasing the dose until efficacy is evident. Side effects have been reported in animals. In a report of 14 dogs in which fluoxetine was used for the treatment of lick granuloma (Raboport 1992), side effects in 4 dogs included lethargy, anorexia, and hyperactivity. Another study (Melman 1995) reported these same side effects as well as polydypsia, diarrhea, and increased or decreased appetite. At least 50% of animals appeared to develop some type of side effect, although side effects were described as "mild." Side effects reported by owners in a study of fluoxetine for treatment of canine dominance-related aggression included fatigue, lethargy, and decreased appetite (Dodman and Mertens 1995).

CLINICAL INDICATIONS. Probably no behavior-modifying drug has received more attention in the veterinary and lay literature than fluoxetine (Kauffman 1994; Marder 1995). Despite the plethora of opinions and testimonials regarding the efficacy of this drug for treatment of animal behavioral disorders, few scientific studies exist. Efficacy for treatment of lick granulomas is supported by a double-blinded crossover study (Rapoport et al. 1992). One-third of the animals studied did not repeat the abnormal behavior when fluoxetine was discontinued. Fluoxetine also has been studied in an open (nonblinded) study in dogs afflicted with a variety of behavioral problems (Melman 1995). Approximately 65% of dogs with lick granuloma, 100% of animals with separation anxiety, and 85% of animals with tail mutilation disorders responded to fluoxetine. Unfortunately, data were not controlled for other treatments, making interpretation of the success of fluoxetine in this study difficult. Fluoxetine has also been used successfully to treat psychogenic alopecia in a cat (Hartmann 1995) and dominance aggression in dogs (Dodman and Mertens 1995; Dodman et al. 1996).

Monoamine Oxidase Inhibitors

Structure-Activity Relationship. The recognition that the antitubercular drug isoniazid tended to elevate the mood of patients receiving the drug for treatment of tuberculosis led to further discovery of drugs that inhibit monoamine oxidase. The first drugs used were structurally related to hydrazine and associated with marked hepatotoxicity. An attempt was made to synthesize CNS stimulant compounds unrelated to hydrazine but similar to amphetamine. Ultimately, this later effort yielded selegiline (Baldessarini 1996b).

The MAO inhibitors potentially impact a variety of monamines by inhibiting mitochondrial MAO and preventing the subsequent degradation of monoamines, most notably dopamine. Most of the clinically relevant drugs are nonselective toward two major enzyme groups (Baldessarini 1996b), which are characterized by different substrate specificities. MAO-A prefers serotonin and is inhibited by clorgyline, whereas MAO-B prefers phenylethylamine and is inhibited by selegiline. Selegiline is the only currently used MAO inhibitor characterized by selectivity. Because it targets MAO-B, it is relatively selective for dopamine. It is approved for use in dogs for treatment of pituitary-dependent hyperadrenocorticism (purported to be a dopamine deficiency). Binding to the MAO is irreversible, and recovery from effects requires synthesis of new enzyme. In human patients, this appears to require 1–2 weeks. Metabolism occurs more slowly in geriatric patients (Baldessarini 1996b).

Pharmacologic Effects. The effects of the MAO inhibitors occur on systems affected by sympathomimetic amines and serotonin. Although as a class MAO inhibitors affect a number of other enzyme systems, generalizations to the class do not necessarily apply to selegiline. Selegiline potentiates dopamine in selected neurons and has been approved to treat Parkinson's disease in humans and cognitive dysfunctions in animals, conditions assumed to be associated with dopamine deficiency. Selegiline also scavenges oxygen radicals and reduces neuronal damage due to reactive products of oxidative metabolism of dopamine and other compounds (Baldessarini 1996b). A delay in the therapeutic effect up to 2 or more weeks characterizes the use of selegiline. Reasons for the delay are not known (Baldessarini 1996b).

Clinical Pharmacology. The MAO inhibitors are readily absorbed following oral administration. Maximal inhibition occurs within 5–10 days. Despite a long biological activity, efficacy appears to decrease in human patients if the drugs are administered at an interval longer than 24 hours (Baldessarini 1996b).

Side Effects and Drug Interactions. Selective MAO inhibitors appear to be safe. However, severe and potentially fatal interactions have been described when MAO inhibitors have been combined with other antidepressants. Particularly problematic is the combination of MAO inhibitors with drugs that inhibit the reuptake of serotonin (see the discussion on the serotonin syndrome of TCAs). Other drugs with which MAO inhibitors may interact include meperidine and precursors of biogenic amines. Selective MAO inhibitors such as selegiline are not necessarily safer than the older or nonselective inhibitors when combined with other drugs. Hypertensive crisis, a serious side effect that occurs when aged cheeses containing tyramine (a bacterial monoamine by-product) are ingested in the presence of nonselective MAO inhibitors, does not occur with selective MAO inhibitors such as selegiline.

Anxiolytics

Pharmacology. The primary anxiolytics used in veterinary medicine are the benzodiazepines (Chap. 16), including diazepam, its metabolite oxazepam, clorazepate (metabolized in the stomach to *N*-desmethyl diazepam, a major metabolite of diazepam), lorazepam, alprazolam, and clonazepam. The assumed mechanism of action of these drugs is GABA-minergic through interaction with the $GABA_A$ receptor. The anxiolytic effects are separate from the general CNS depressant effects caused by these drugs. Their central effects are somewhat dose dependent. Sedative effects occur at low doses; as a result, excitement is tempered. Antianxiety effects are evident at moderate doses and are beneficial to social interactions. At high doses, hypnotic effects become evident. Sedation becomes profound at high doses and ataxia is evident and sleep is facilitated (Overall 1997). Decreased skeletal muscle activity (particularly of value in seizuring animals) is central in nature and is independent of sedative effects. Cats appear to be more prone than dogs to muscle relaxation (Overall 1997). Benzodiazepines may distribute differently in cats, with extensive binding of diazepam and its major metabolite, desmethyldiazepam, in the brain (Placidi et al. 1976).

The effects of the benzodiazepines reflect in part metabolism to active, inactive, and potentially toxic metabolites. If efficacy reflects formation of an active metabolite (e.g., desmethyldiazepam), accumulation may be necessary before maximum effects are seen. Lorazepam and oxazepam have short elimination half-lives in human patients and are metabolized by phase II (glucuronidation) enzymes. Thus, metabolites of these drugs are not likely to be active or toxic.

The elimination half-life of many benzodiazepines in general is short. Efficacy can be prolonged by metabolism to active metabolites. The drugs are categorized by their duration of effect in humans, although it is not clear if the same categorization will apply to animals. Clorazepate is available as a sustained-release product that can be administered less frequently.
